Sculpture was practised in Persia with very limited success. Various circumstances conspired to retard its progress. The Persians, disapproved of statues for religious purposes; that is, as objects to which worship should be offered. Not believing, as the Greeks did, that the gods had the human form, they admitted no representation of the deity, and allowed fire and water to be the only symbols or emblems of the divine power. It is said that Xerxes destroyed the temples of Greece at the instigation of the Magi, who exclaimed against the impiety of those who presumed to enclose within walls the gods to whom all things are open and free, and whose appropriate temple is the whole universe. Wherever they appeared as conquerors, the effects of this opinion were exhibited; and in Egypt, as well as in Greece, they gave full indulgence to the iconoclastic fury. It is not easy to determine the date of such sculptures as appear on Persian buildings. Those which decorate the structures at Persepolis represent religious processions chiefly, and sometimes combats both of men and beasts. In none of them is there any approach to a representation of the naked human figure. Their figures, enveloped in long heavy draperies, are deficient in grace, variety of action, and character. At a later period of their history some innovations seem to have been permitted, but these were not of sufficient importance to raise their art to any degree of excellence. The low measure of their attainments in this respect, and the general want of taste in art, are strikingly exhibited in the gold coins called *Darics*, which display as much poverty of design as meanness and clumsiness of execution. It has been thought that Persian art received some additions or modifications after the return of Cambyses from Egypt, when he probably was accompanied by some of the artists of that comparatively cultivated nation. There is however nothing in any of the monuments that remain which is evidence of this influence. In the treatment of the termination of the hair in small round shell-like knobs, and in the parallelism and uniformity of the long draperies, there is a strong resemblance between the styles of the Persian and early Greek and Etruscan monuments. If this is anything more than a general characteristic of primitive art, it only proves that the Persians were at one period not far inferior to their neighbours, but failed to make that progress in design and execution which eventually led to the perfection of art in Greece and Asia Minor.

In Egypt, on the other hand, distinct as is the quality of its art from that of Greece, sculpture was practised on a scale and for purposes that give it an irresistible claim to our interest. From all we read in ancient authors, and from all that modern research has brought to light, the Egyptians were learned, intelligent, industrious, and wealthy. Neighbouring nations considered Egypt as the centre and the source of all knowledge; and "the wisdom of the Egyptians" passed into a proverb. Of the power and the ingenuity of the Egyptians, even in the most archaic times, some idea may be formed from the magnitude and character of their remaining monuments of architecture and sculpture, some of which, of a finished style of art, are considered to be not only of a much earlier date than any known works of other countries, but older than any historical record that we possess. The date of the foundation of Thebes, the capital of Upper Egypt, and of Memphis, the capital of Lower Egypt, is undetermined; but it must be of a very high antiquity. At Karnak (a portion of Thebes lying on the Arabian side of the Nile) there are remains of sculpture which bear the name (Osirtasen) of a monarch supposed to have been contemporary with Joseph: and many of the ruins are attributed by archaeologists to a date long antecedent to that king. These monuments are mentioned merely in proof of the great antiquity of sculpture among the Egyptians, and as affording the opportunity of comparing the peculiarities of the style of art at that early time with that of works of later date.

Winckelman, Millin, and Fea have thought it possible to distinguish different periods, or epochs, in the history of Egyptian sculpture; but they have not agreed in their classification. This is not to be wondered at, when the general resemblance of style that pervades all Egyptian design is considered. In the course of ages, and especially under some of the more ambitious and enlightened of their kings, a grander style of form and greater variety of composition were indulged in. Still, the very slight variations that were made (for, considering the space of time over which the history of Egypt, as a flourishing nation, extends, they may truly be called slight) render any attempt at a satisfactory classification, or reduction of changes to chronological periods, almost hopeless. The only division of epochs of art in Egypt which is not open to dispute is, first, that of an original and preserved standard which, with slight variations and modifications, existed from the earliest date of art in the country down to the time of the arrival of the Macedonian Greeks in Egypt, that is, till about 330 B.C. The Greek dominion in Egypt constitutes the second period; and the style of art may perhaps not inappropriately be called Graeco-Egyptian, as it certainly was influenced by the taste introduced by that people. The next and last period may be termed the pseudo-Egyptian, or imitative period; and dates from the time of Hadrian, or about A.D. 130, when the Romans adopted many of the superstitions of the Egyptians, and added some of their divinities to their own extensive mythological calendar. This love of novelty, or subserviency to the caprices of their emperor, filled the cities and villas of Italy with statues of Isis, Osiris, and other personages and objects of Egyptian worship. No advantage, however, was gained by Egyptian art in consequence of the springing up of this fashion in Rome. The great endeavour was rather to give all design an Egyptian character, than to elevate the character of Egyptian art by the introduction of a superior taste either in form or composition. The most favourable specimen of the mixed style is the fine statue of the Egyptian Antinous, as it is called; but, founded on caprice and false principles, the Roman or pseudo-Egyptian manner soon fell into disuse, and has never been resumed. It will be remarked that in all the changes of circumstances to which we have referred, and by which the political condition of Egypt was materially affected, no sufficient alterations occurred to destroy the peculiar and distinctive character of Egyptian art, which exists in all its force, whether the works be of the most remote archaic period and of the whole range of time to Alexander the Great, of the time of the Ptolemies, or even the still more modern period of Hadrian.

It is indeed matter of surprise that a nation so celebrated as the Egyptians for superior intelligence, and of such long experience in the practice of the arts, should have made so little progress in them; and the phenomenon would be quite inexplicable if we were not acquainted with the nature of their institutions, and the check which was thus opposed to their advancement beyond a certain limit. The common speculations that have been offered with the view of accounting for the acknowledged inferiority of the Egyptians to the Greeks are altogether unsatisfactory, even if the facts upon which they are founded could be admitted. Some have supposed the absence of grace and the stiff uniformity of action in Egyptian design to be owing to the want of beauty in the natives of Egypt. Others have imagined that the artists' want of knowledge of anatomy, and there being no public games in which they could study the human figure, are sufficient to account for this inferiority; attributing to physical causes alone that which was effected by very different influences. The art of sculpture especially seems to have been employed exclusively for religious purposes. The priests, an hereditary body, systematically enforced the preservation of ancient usages, and confirmed their hold upon the respect, obedience, and veneration of the people by not suffering any innovation upon old established forms. The whole population was divided into castes, and a calling or profession was exercised from generation to generation. The sons were all obliged to follow the steps of the father. The order of these castes is variously stated by different writers. The sacerdotal, of course, ranked first. According to Synesius, the profession of an artist was not exercised by common or illiterate persons, lest they should attempt anything contrary to the laws and regulations regarding the figures of the gods; and Plato, in his second book of Laws, says, "they never suffered any painters or statuaries to innovate anything in their art, or to invent any new subjects or any new habits. Hence the art remains the same; the rules of it the same." Here, then, we see the real cause of the duration through a series of years of one unchanged style of art. The origin of the form preserved through so many ages is declared by its extreme simplicity. The earliest attempt at representing the human figure would be marked by the absence of action; and this is the characteristic of all Egyptian statues. The figure is upright, or kneeling, or sitting. The legs are close together, and the arms are attached to the body. This, then, became the established type; and though some slight movement was occasionally allowed, as in advancing one foot before the other, it hardly can be said to relieve the so improved figure from the stiffness of the more primitive standard. That there was a capability in the artists for mechanical excellence is amply proved by the more elegant forms that sometimes are met with even in Egyptian statues, but more especially in those works where they could without impropriety indulge their fancy. The heads of divine personages occasionally beam with majesty and grace; and in the examples in the British Museum of Egyptian monuments, whether in the head of the so-called Young Memnon, or in the Prudhoe Lions and other representations of animals, or in some of the compositions portraying scenes of active life, the student will perceive that some other cause than want of feeling or skill must have operated to prevent the sculptor of Egypt from arriving at the same eminence in art, that was attained by the artists of Greece. The stiff and limited action of Egyptian statues has already been noticed. To this must be added, that the figures of men are usually naked, excepting that a sort of apron is folded across the loins; while those of women are represented dressed in a long and simple garment fitted close to the body. This covering has no folds in it, and can only be distinguished from the figure by a slightly raised border at the neck and feet. The form of the breasts is sometimes indicated on the dress by their natural projection being circumscribed by an indented line. One of the most interesting specimens of Egyptian sculpture is now in this country. It is generally known as the head of the Young Memnon, though it has no claim to that title, which was given it from a mistake made by Norden, the traveller, who visited Egypt in 1737. This bust is formed of a single block of fine-grained granite, containing two strata of colour, one portion being of a red, the other of a gray (or blue) cast. Though it possesses all the characteristics which so eminently distinguish Egyptian sculpture,—the flat eyebrows, projecting eyeballs, the rounded nose, thick lips, and the ears placed high up,—this head claims admiration for beauty of outline and the peculiar sweetness of its expression. It offers a remarkable exception to the general rule of Egyptian design, and shows, what has before been hinted at, that there was the power of representing beauty both of form and sentiment, if room had been allowed for its exercise. In working basso-rilievo (and pictures) the Egyptian artists decidedly ventured beyond the limitations to which they seem to have been confined in representing insulated figures. Almost all the temples and tombs that have been explored are richly decorated with sculptures in the peculiar style of rilievo to which allusion has been made in the introductory part of this article; and although they do not materially differ in the general style and character of art, they are sufficiently varied in the mode of treatment to warrant this distinct notice of them. The most striking difference from the insulated figures consists in the superiority, as well as extent, of design and composition. This is particularly observable in the Theban remains, to which attention has been directed by Wilkinson, Rosellini, and others who have illustrated the history, arts, and customs of the ancient Egyptians. Wilkinson, speaking of Luxor and Karnak, observes as to the decorations of the temple, "The principal historical sculptures are on the exterior of the great hall. . . . . . The upper compartment represents the king attacking a fortified town situated on a rock, which is surrounded by a wood, and lies in the immediate vicinity of the mountains." In another compartment the king is again the hero, and is represented slaying the chief of the enemy with his sword, having first wounded him with his spear, and entangled him with his bowstring. The author observes here that the drawing of these figures is remarkably spirited. After other series or compartments, in which the Egyptian monarch is seen scattering death among his enemies, is a representation of his return, and the presentation, by him, of captives and spoils to the deities of Thebes.

All colossal works in Egypt are of basalt, porphyry, granite, or sandstone, though Herodotus (ii. 143) tells us that at Saïs and at Thebes there were statues, of large dimensions, of wood. We are not aware that any large statues have been found made of metal. The British Museum possesses three bronze figures which merit attention, as they exceed the usual dimensions of such Egyptian works, being about three feet high, and gilt. The substance or thickness of the metal is not great, and the interior is filled up with stucco or plaster. The gilding, some of which is well preserved, both in surface and colour, seems to have been applied as a wash, the bronze having first been entirely covered with a coat of plaster about as thick as a card.

The clean execution and exceedingly fine surface observable in the sculptures of Egypt have attracted the attention of practical judges, and led to the conviction that the Egyptians must have had great knowledge in the arts of hardening or tempering metal, to enable them to execute such highly-finished works in the most obstinate and brittle materials. It is a remarkable fact that when the colossal head before alluded to as the Young Memnon was placed in the British Museum, and it was necessary to cut some holes in it for the insertion of iron cramps to unite some of the broken fragments, the hardness of the granite was so great that six or eight blows rendered the mason's tools (which were tempered more highly than usual) totally useless.

The facilities that are now afforded the student and public for examining authentic monuments of Egyptian art in the extensive and valuable collection in the British Museum, render it unnecessary to dwell at greater length upon the peculiarities of that school of design. That their works are wanting in the grace, the flow of lines, and the beauty united with repose, that constitute the charm of the best Grecian sculpture, must at once be admitted; but the simplicity and clearness of intention in their more extensive compositions, and the sublime grandeur, repose, and dignity of their colossal statues, so appropriate to their mystic and religious purposes, will always ensure their being considered amongst the most interesting monuments of past ages.

Assyrian Sculpture.—Until so recently as 1843, nothing was known of the arts of the ancient Assyrians beyond the references to the splendid palaces filled with statues and painted bassi-rilievi on the walls, of vast size and admirable workmanship, in the Old Testament and in ancient Greek authors. But in that and following years a surprising number of the monuments themselves were brought to light by the fortunate researches of MM. Botta and Layard, and their successors, and transferred to the British Museum and the Louvre. The buildings in the buried ruins of which the Assyrian sculptures were found have been described, and the sculptures themselves noticed, under NINEVEH, ARCHITECTURE OF; here, therefore, it will only be necessary to indicate briefly their character. All the sculpture yet found, with the exception of a few bronzes, consists of slabs, often of colossal dimensions, on which are carved figures in relief, and with which the walls of the palaces were faced both inside and out. In date they are believed to range from the reign of Sardanapalus, B.C. 930, to the destruction of Nineveh, B.C. 625. As Nineveh was founded 1200 years earlier, they do not therefore represent the archaic period of Assyrian art. The existing examples appear to belong to three distinct periods. The earliest are those brought by Mr. Layard from the great palace and adjoining buildings in the north-west quarter of Nimroud, and now in the British Museum; they belong to the age of Sardanapalus, or about 930—902 B.C. They consist of colossal human-headed winged lions and bulls, personages from the Assyrian mythology, and other single figures; of representations of battles, sieges, the passage of rivers, the chase, the great king sacrificing, &c., cuneiform inscriptions being often carved quite across the slabs, without any regard to the figures. As works of art, they do not take a very high rank: the drawing of the human form is inaccurate, the muscles are exaggerated; there is utter ignorance of perspective; and the artists were evidently bound, like the Egyptian sculptors, to certain strict conventional rules. Yet it is impossible not to be struck in these older works with a certain largeness and severe grandeur of style and power of imitation. Here, as indeed throughout, Assyrian art seems to hold a sort of middle place between Egyptian and Grecian art. The slabs found at Khorsabad by M. Botta, and deposited in the Louvre, belong to a middle period, that of the 8th century B.C. Less severe and perhaps inferior in grandeur to the older works, they exhibit more refinement of execution. The Kouyunjik monuments in the British Museum are of the third period, or between B.C. 721 and 625. The slabs contain historical records, hunting scenes, &c., similar to those of earlier date, with some rather different in character, representing Sennacherib superintending the construction of some great architectural works, and directing the removal of colossal human-headed bulls. The scenes represented in the slabs of this third period are more varied in character, the execution is more careful, the figures are more minute and more accurate in the details,—in the animals, especially, the minute accuracy and knowledge of animal nature are quite remarkable,—but the largeness and grandeur of the older works are wanting. The slabs of each period are chiefly of alabaster, but some of the latest date are of the harder native limestone. All of them appear to have been painted with the most brilliant colours they were the figures pourtrayed with vermilion, exceeding in dyed attire, all of them princes to look at, described in the sacred scriptures.

Etruscan Sculpture.—The Etruscan is the next school of sculpture that claims attention. The history of this nation is involved in great obscurity. The appellations of Tuscan and Etruscan were foreign to them, and Etruria was a Roman term. The more ancient name by which they were called was *Rasenæ* ('Ρασηναι). Their later history is chiefly known from their connection with other nations. [ETRURIA, in GEOG. DIV.] An examination of their sculpture, as founded on the numerous existing monuments, almost seems to connect them, in a greater of less degree, with the Greeks. Whether the Etrurians at any time possessed a mythology and style of design on which Greek "myths" and forms were subsequently engrafted, or whether each nation retained principles originally common to both, is not important in this part of our inquiry. The supporters of the more remote antiquity and superior intelligence of the Etrurians have supposed it possible that this people, instead of being taught by them, were at one time the instructors of the Greeks, amongst whom, in consequence of their wars, internal divisions, and other disturbing causes, the arts were neglected, and probably suffered to fall to decay, while Etruria had enjoyed a state of comparative repose, favourable to the advancement of the arts. Among the great difficulties with which this part of the subject is embarrassed, is that of establishing with any certainty the dates of the settlement of Greeks in Etruria. It certainly is remarkable that the cinerary urns found in sepulchral chambers often have represented on them subjects whose meaning is unknown, and which seem to have no affinity at least with the *post-Homeric* Greek mythology; and so far the practice of art and a class of symbols seem to have existed in Etruria, either essentially its own, or, if ever shared with others, so ancient that all record of it was lost, excepting as it appears on these older Etruscan monuments.

The history of the known Etruscan school of sculpture is therefore necessarily founded on the character of the majority of existing specimens; and in these the recurrence of similar subjects and personages, resemblance of costume, and the common form of many of the letters of the Etruscan and Greek alphabets, distinctly establish the fact of some communication between the two nations. Lanzi ('Notizie sulla Scultura degli Antichi') divides the art of Etruria into epochs or periods, and considers the second to be that which was influenced by colonies from Greece; and it is this influence which is so observable in the monuments referred to.

In observing, however, that all or nearly all the specimens of Etrurian art that have reached our times indicate a connection or intercourse at some period between that country and the Greeks, it may be well to repeat a remark that has incidentally been made in a former part of this history,—to caution the student from too hastily attributing to different nations a common origin of design, from the mere similarity of certain forms and corresponding particulars of execution which may perchance be recognised or discovered in their primitive attempts at art. It must always be borne in mind that this appearance is often nothing more than the general characteristic of all art in its infancy; the same, or nearly so, in Greece, in India, in Etruria, as in all other countries. Lanzi observes, in speaking of the sculpture of this school ('Notizie sulla Scultura degli Antichi'), that a distinction must be made between works in the Etruscan style and works simply executed by Etrurian artists. The "Etruscan style" was a peculiar manner of treating art. It was designated by the Latins "Tuscanicus;" and all works executed in this manner were termed "opera" or "signa Tuscanica." That this distinctive character of school existed, and was recognised as a peculiar feature in art, is confirmed by a passage in Quintilian, in which that writer is particularizing the style of some of the great sculptors of Greece, and showing the changes or progress that distinguished the earlier from the later masters. He says, "Callon and Egesias made their statues hard" (a technical term meaning stiff and severe) "and nearly approximating to the Tuscan figures. Calamis made his works less rigid." (Quintil., 'Orat.,' lib. xii., 10.) The peculiar characteristics of the Etruscan style,—the *signa Tuscanica,*—are an affectation or exaggeration in the general actions and attitudes, and meagreness of treatment in the details. In the heads, whether of male or female figures, the hair is usually stringy; or plaited, and falling in long tails or lengths. The hands are placed in the least natural position for the purpose on which they are employed, and the ends of the fingers are often turned up in the most unnatural and therefore ungraceful manner. The draperies are cast without any regard to masses or agreeable forms, and always appear as if they had been put on wet and starched, and had stiffened in drying; the edges are very much shown, and in the falling or perpendicular views appear in regular and corresponding zig-zag lines. Many points of resemblance to the above works of the *signa Tuscanica* will be found in early Greek art, especially that of the Æginetan school. With these, however, this indication of primitive style passed away as the knowledge of art advanced, while the Etruscan manner was retained, and even imitated in many works of a much later period than the original Tuscan, and by artists belonging to schools of a more perfected taste. As a general remark, it may be observed that productions in the Etruscan style are very deficient in beauty. They neither exhibit the repose and simplicity which, notwithstanding its other deficiencies, give dignity to Egyptian, nor the fine forms and sentiment which ennoble Grecian sculpture; and whatever interest they excite is derived rather from the value that attaches to them in an archæological point of view, than from any merit that they possess as works of art.

It has been observed that some Etruscan works are found to differ from these in the style of their execution. This is particularly observable in the recumbent figures that have been discovered in the Volterran and other Etruscan tombs and hypogæa. Some of these are small, but many are of large size, and usually decorate the lid of the coffin or sarcophagus in which the ashes and sometimes the body of the deceased were deposited; closely resembling in this respect the style of monumental sculpture in Europe in the 15th and 16th centuries. In these figures there is a totally different character, both in form and expression, from the true Etruscan monuments. The heads frequently possess great beauty; there is often a strong character of nature in them, and it seems probable that they were intended to be portraits of those whose tombs they surmount. Many of them show marks of having been painted. The age of these works is undetermined. From the locality in which they have been found, and from the inscriptions which they bear, they would seem to belong to remote times of Etruscan dominion. In other respects, as in the general heaviness of the forms and clumsiness of drapery, they call to mind the style of art of a low Roman period; to which time, indeed, some antiquaries have at once assigned them. The question is not unattended with difficulty. There is every reason to believe that the ancient tombs of Etruria had been invaded, and in many instances opened and plundered, long before they were rediscovered by our modern archæologists and collectors. It is also probable that many of them have been used as depositories of the dead by a people much more modern than their original constructors. Objects have been found in them of various ages, from which it would appear either that many of the tombs and sarcophagi are really of a later date than usually has been supposed, or that the ancient burying-places have been used for the dead of a more modern race.

It is worthy of remark, as it may account in a great measure for the distinctive quality of Etruscan art, that Etruria, like Egypt, was ruled by a powerful hierarchy. Their chiefs, *Lucumones*, were priests as well as temporal rulers, and they may, like their Egyptian brethren, have exercised some influence in directing art, and in preserving from innovation the forms once consecrated by religion. It is at the same time probable that this influence was not so restrictive in Etruria as it was in Egypt; for the varieties that are found in works of art prove that the artists here took greater liberty than was permitted to those of Egypt. This appears to be the most reasonable way of accounting for the continuance of a distinctive style and limited progress of design among a people who were eminently clever (φιλοτεχναι) and ingenious. Considered in this point of view, Etruscan sculpture holds a position of great interest in the history of art. It is impossible not to recognise in it the connecting link between two systems, namely, the practice of art for hieratic or purely sacred purposes, and that more liberal and general development of it which, under the later and more refined Greeks, was directed to the illustration of the most poetical and sublime conceptions through the medium of the most beautiful forms. Of the great extent of their practice in sculpture a sufficient proof is afforded by the fact mentioned by historians that when after having sustained long and expensive wars against the Romans, the Etrurians were finally subdued by them, and became a Roman province (about 280 B.C.), two thousand statues were taken by the victors from Volsinii alone. (Plin., 'Hist. Nat.,' xxxiv. 7.)

The Etrurians were famed for their skill in making vases, and different towns became celebrated for peculiarities of manufacture. (Plin., 'Hist. Nat.,' xxxv. 45.) There is however reason for believing the greater number of painted *terra-cotta* vases, usually called Etruscan, from being first discovered in Etruria, to be Greek. Their subjects, their style of painting and design, evidently connect them with that people; and it has been observed, that though the Etrurians inscribed every other work of art with their own characters, there is scarcely an instance of a painted vase with any other than a Greek inscription: some of these may, however, be imitations of Greek vases. The Arezzo (Arretium) vases are of a fine clay of a red colour, but the figures are in relief: many of these are of a comparatively late period, and bear Latin inscriptions. (Inghirami.) The arrival in Etruria of Demaratus with artists from Corinth has been assigned as the date of the introduction of the art of making vases, and of other processes in the plastic art. It is, however, more probable that they only effected some changes in the style of design that already prevailed; for modern discoveries seem to establish the existence in Etruria of a manufacture of cinerary urns and vases long anterior to the appearance of the refugees from Corinth. (Lanzi, *l. c.*; Winckelman, 'Storia della Scultura;' Mrs. H. Gray, 'Tombs of Etruria.)

The Gallery of Antiquities at Florence contains several extremely curious specimens of Etruscan sculpture, especially in some figures of large size in bronze. Some of these have inscriptions on them. The bronze she-wolf, preserved in the Capitol at Rome, is also a remarkable example of ancient art in the Etruscan manner. The extensive discoveries that have been made in different parts of Tuscany of late years have likewise added greatly to our knowledge of the Etruscan art and customs, and have enriched the museums of Rome, Naples, Florence, and even England, with most interesting records of this remarkable people. The remains preserved in these and in private collections are well worthy of attention, but a detailed description of them belongs rather to the general history of the country and its antiquities.

The works in sculpture of the Etrurians are chiefly in *terra-cotta*, stone, and bronze; and the most ancient tombs have supplied some exquisitely worked ornaments in gold, as well as larger pieces of armour of the same costly material.

Greek Sculpture.—In the preceding pages we have had rather to notice its existence than to trace the progress of sculpture; for, with very limited exceptions, its practice was under circumstances so little favourable for its improvement, that it is scarcely possible to connect it, in any way, with the refined pursuit which it afterwards became in the hands of the Greeks. In other countries it never advanced beyond certain limits; mere representations of objects were produced seldom elevated by sentiment or feeling; and if, sometimes, the rudeness of first attempts at form was overcome, the art still remained in fetters. In Greece, on the other hand, sculpture soon rose superior to all those prejudices that would have restricted its advancement. With this gifted people it became something more than a merely mechanical pursuit. It was here that the conceptions of sublime and glowing fancies were embodied in the productions of what may truly be termed a race of poet-artists. Writers have endeavoured to account in various ways for this universally admitted superiority of the Greeks over every other nation among whom the fine arts had been practised, and usually have attributed their success to such physical causes as a fine climate, or the prevalence of beautiful forms, or to the public exercises so general in that country; or to the kind of government in those communities in which the arts were most successfully cultivated. Valuable as some of these conditions must be allowed to be towards the perfection of art, they are by no means sufficient to account for an excellence which, even amongst the Greeks, was both extremely partial with respect to locality and extent, and limited as to its duration. Nor were those particular states in which the arts of design most flourished peculiarly favoured beyond others in the causes supposed to contribute to that excellence. The climate of Attica, it is admitted, was unequal; and though vegetation appeared in the greatest luxuriance in some spots, in others the soil was barren and naked. With regard to beauty, too, there is no reason to believe that the people who most excelled in the fine arts (namely, the Athenians) were distinguished beyond all other Grecians for this quality. Cicero, indeed, makes a very remarkable observation which would go far to prove that the contrary was the fact. He says, speaking of the crowd of young men whom he saw at Athens, how few there were who were really handsome. ('De Nat. Deor.,' lib. ii., c. 79.) And it is curious also that of all the women whose celebrity for beauty has reached us, not one appears to support in this respect the honour of Athens. Phryne was a native of Thebes, Glycera of Thespiæ, Aspasia was born at Miletus, and when Zeuxis, the painter, desired to procure the most beautiful models for his Aphrodite, it is said he produced his masterpiece from the study of seven virgins of Crotona. It is not intended to deny the existence of beautiful forms amongst the Athenians, but simply to show that it is not to this exclusive possession that their success in the imitative arts can justly be attributed. The admiration of beauty amongst the Lacedæmonians is admitted (Ælian, 'Var. Hist.,' xiv. 27; and 'Athen.,' xii. 12); but the fine arts were not permitted to be practised in Sparta. In other parts of Greece also personal beauty conferred a title to distinction; the priests of the young Zeus at Ægium in Achæa, those of the Ismenian Apollo, and the boys who walked in procession at the festivals in honour of Hermes at Tanagra, were youths to whom a prize of beauty had been awarded (Paus., vii. 24; ix. 10. 22); but no school of art arose out of this which at any period equalled, or attempted to equal, that of Athens. It is scarcely necessary to allude to the question of government. The arts flourished where the most different forms existed. Corinth held a secondary rank among the cities of art, while Athens and Sicyon were in the first. Indeed, if wealth, pomp, and luxury had been necessary, or alone favourable, for the success of art, it would have been exhibited among the splendid communities of Asia, and not been left to its comparatively tardy development in the small, scattered, and often disturbed states of Greece. It was not to any of these accidents, either singly or collectively, that the perfection of Greek sculpture was owing. It was the principle upon which, among that people, imitative art was founded (and upon which it was practised throughout all its stages), that led to its excellence. The whole secret of the superiority of the best schools of Greece was in their making nature, in her most perfect forms, their model,—the only means by which perfection in art can be attained. As soon as they acted upon this knowledge, their sculpture became almost as divine as their great examplar.

Judging from their poetry, and from their art, whether in their sculpture or their painting, it would seem that the Greeks had an intuitive sympathy with beauty. The artists seem to have been careful never to lose sight of this principle, by expressing any passion or feeling under forms at variance with the simple laws of beauty. All extremes of expression are studiously avoided, and they appear to have chosen only those subjects for representation which allowed them to keep within these bounds. Pliny ('Hist. Nat.,' xxx. 37) mentions an artist who had an opprobrious nickname in consequence of painting low and common place subjects; and the Thebans had a law which subjected artists to a fine if their works were inferior in beauty to the objects which they professed to imitate. (Ælian, 'Var.,' iv. 4; Junius, 'De Pict. Vet.,' ii. 4; Lessing, 'Laocoon,' ii. p. 12.) This natural sensibility to the charm of beautiful forms was encouraged and assisted by the habits of the people. The gymnasia, or schools, in which young men were trained to take part in the public games, were frequented by all classes. Statesmen, philosophers, poets, and artists were in the habit of attending them, and were thus accustomed to see the human form in all its varieties, whether draped or naked, or in repose or in action; and while the sculptor was filling his mind with the beauty and capabilities of the human figure, the spectator was acquiring the knowledge that enabled him to become a competent judge of imitative art. The importance attached to distinction in these games rendered the education of the young men a subject of great care. Every means were resorted to in order to increase the elegance, the strength, the suppleness, and the active powers of the body; and the sculptor especially benefited by having constantly before him the finest forms that exact discipline and judicious training could produce. He was thus taught to seek the causes of the superiority of the victor in the race or the wrestling match; and by comparing or contrasting the different properties most generally found to exist in the conquerors in the various classes, to adopt those qualities in whatever characters he might be called upon to represent. The deep and spacious chest and broad shoulders of the brawny wrestler gave the type or distinguishing character of Heracles, and the class in which physical strength was to be exhibited: the clean legs, small well-knit joints, and light proportions of the victor in the foot-race, furnished the character of form of the messenger of the gods; while the union of strength and agility in the athlete, taught the sculptor how to make those combinations which eventually resulted in what is termed *ideal* beauty,—the statues of gods, demigods, and heroes. Having this access to the best models, and exercising his art under the eyes of critics who, from habit and observation, were as well acquainted as himself with his standard, it is not surprising that the sculptor of Greece acquired a facility and a power of representing every class of form unattained by any other people, and which have rendered the terms Greek and perfection, with reference to art, almost synonymous. The high purposes to which sculpture especially was applied, and the general interest that was felt in all works that were produced, account for the success with which the art was practised. The mind of the sculptor was enlarged while he reflected on the appropriation of his work and the great objects of his labours. His was not the ambition of present praise or profit. He felt, and truly felt, that his art, properly practised and rightly understood, was capable of producing great moral effects upon those who were to contemplate them; and consequently, in the best period of Greek art, the appeal was always made to the higher feelings rather than the mere senses. The artist did not produce his works to gratify a patron, but to improve a people; and whether they were destined to the temple, the grove, the portico, or the place in which the public games were celebrated; whether, like the Zeus of Olympus, they were intended to excite religious impressions of the majesty of the gods; or, as in the *icones* (or portrait statues) in Altis, to stimulate the energy of the youths of Greece to gain distinction in the public games—the sculptor felt, and he acquired power as he was impressed with the ennobling idea, that he was contributing to a great end. This is the principle of the success of the arts in Greece; and in the presence or absence of this recognition of the public utility of art, may be discovered the causes of its comparative success or failure in other nations and in later times.

In Greece, as in other countries, the earliest attempts at imitative art were extremely rude. Pausanias, who travelled in Greece about A.D. 170, mentions that at Pharæ in Achæa thirty quadrangular blocks of stone were worshipped, or at least honoured, as the symbols or representations of certain divinities. At Thespiæ Hera was thus recognised, and at Sicyon Artemis Patroa was represented by a column, and Zeus Milichius by a pyramid. (Paus., vii. 22; ii. 9.) The ancient statue, if it can be so called, of Aphrodite of Paphos, with others that might be referred to, were mere columns or stones set upright. The next step in art was in the attempt to characterise these shapeless symbols by giving them a human form. The upper part was shaped into the likeness of a head, and, by degrees, arms and legs were marked out; but in these early imitations of the human figure the arms were doubtless represented closely attached to the sides, and the legs, though to a certain extent defined, were still connected or united in a common pillar, as in the statues of the Egyptian school.

The history of Greek sculpture may be divided, generally, into four periods, each of which is illustrated by existing works bearing unequivocal marks of the progressive changes which attended the practice of the art from its rise to its decline. These greater divisions or periods might perhaps easily be subdivided into smaller parts; but, as the present object is to give only a general and comprehensive view of the history of Greek sculpture, it seems better to confine ourselves to a few great divisions. The student who desires a more extensive acquaintance with the subject will find ample information in the numerous valuable works that have appeared of late years, as well as in the opportunities that now exist of examining the remains of Greek art of all ages which are preserved in the museums of this and other countries. The four principal sections into which ancient Greek sculpture may be divided are—the Archaic, or most ancient period; the Phidian; the Praxitelian, which includes the period of Lysippus; and fourthly, the age of its decline.

The First period embraces all the uncertain age, of which little is known but what can be gleaned from the traditions preserved in ancient writers. It may be considered to extend to the commencement of that great change in the style of art which had its consummation in the school of which Phidias was the head. The Second division includes the period during which sculpture was practised in the grand or sublime style, and during which the scholars of Phidias executed their works on the principles which he taught and illustrated. The Third period is characterised by a more rich and flowing style of execution, as well as by the choice of softer and more delicate subjects than had usually been selected for representation. In this the beautiful was sought after, rather than the sublime. Praxiteles may be considered the first sculptor who introduced this more sensual, if it may be so called, style of art; and Lysippus contributed to advance it by the peculiar fulness, roundness, and harmonious general effect, by which it appears that his works were characterised. The Fourth and last period in this classification is that of the decline of sculpture; when, although the excellence of preceding schools was still admitted and often maintained, not only no advance was made, but artists were frequently led away by the love of novelty of design, or the desire to discover some new road to fame or profit, and neglected the means which ages of progressive improvement had shown to be the best and safest rules of practice. When this was the case, grandeur of style will be found to have given place to littleness, and the beauty and simplicity of general form and character were lost in individuality and minute detail.

The remains of Greek sculpture of the Archaic period are interesting to the antiquary, but they offer few attractions to the lover of the beautiful. Rigid and stiff in action, and rude and inelegant in form, the statues and rilievi of the infancy of Greek sculpture have very little to distinguish them, in these respects, from the earlier attempts of other nations. The first step towards a change was in the attempt to give action; and this was soon attended by fresh peculiarities of shape or figure in the parts. In this stage it will be observed that there is great energy or violence in the general design, with a lumpy or knotty character of form. The general proportions of the figures are thick in comparison with the length of parts. The breasts and shoulders are wide and broad, while the hips are narrow. The thighs and calves of the legs are large and heavy for the knees and ankles, and the feet are long and clumsily shaped. The treatment of the head is peculiar in the sculpture of this early period. The eye is usually long and narrow; and is slightly raised at the outer extremity. The mouth is open, and, owing to a slight curve or elevation at the extremities, has the expression of smiling. On the most ancient coins the hair is wiry, the lines being parallel and close together, in the apparent endeavour to give the effect of the whole by imitating every hair. This was more successfully attempted by executing the hair in masses; some very ancient works exhibit examples of this, where the effect is partially produced by small knobs or lumps. At a more advanced period the hair is executed in a more minute and careful manner, and with a more precise arrangement, combining as it were the particular character of the earliest treatment with the more general effect attmepted in the next stage of art. In this the hair is brought in nearly straight lines over the head, but it terminates in small round curls which are arranged with great regularity, and sometimes in two or three rows over the forehead, extending on each side to the temples and ears. Specimens of these modes of treatment occur in the early tetradrachms of Athens; in the heads of the figures in the statues found in the island of Ægina; and in the sculptures found at Selinunte in Sicily, as well as in other remains of small bronzes and early coins; and there are many examples of it preserved in the collection of antiquities in the British Museum. In male figures the beard, wherever it occurs, is wiry, and exhibits elaborate execution. There is a curious specimen of this in the head of a warrior in a group in the Selinuntine marbles above mentioned (and of which there are casts in the British Museum), as well as in the Æginetan marbles. The draperies in the sculpture of this early time are extremely thin, lying close to the figure (or to the ground, if in reliefs), excepting at the edges of the folds, which are sharp and angular; these are arranged with the greatest precision, opposite folds corresponding as nearly as possible with each other, with the edges shown, and terminating in a sort of regular zigzag series of lines. All these peculiarities are characteristic of the most ancient, or, as we have called it, Archaic art: and whenever imitations of it have been made in later times, these features of action, form, and treatment of drapery have been observed. Sometimes portions only of the peculiarities above pointed out will be remarked in genuine ancient works, but of a later age than that under consideration. The sculptures alluded to as Æginetan offer examples of this; the treatment of the heads being characteristic of an earlier age of the art than the rest of the figures. This is doubtless to be attributed to a feeling of veneration for the older forms and received traditions of certain personages, such as divinities and heroes; and in this respect obedience to prescription marks the Greek as it did the Egyptian and other schools: with the former however it lasted for a limited period only; with the latter it extended throughout their whole existence.

The first sculptors whose names are recorded are Dædalus, Smilis, and Endoeus. The earliest person called Dædalus was descended, according to the ancient traditions, from a royal stock, being grandson of Erectheus, king of Athens. He is said to be the first sculptor who ventured to separate the legs of his statues. He also was the inventor of the saw, the axe, lever, &c. It is impossible to say how much fable and exaggeration have been admitted into the accounts of this remarkable discoverer; and it is equally vain to attempt to distinguish the inventions of the earlier artificers who bore this name, from the improvements introduced at subsequent times by others so called. Dædalus was in all probability a general title, for some time, given to any distinguished mechanist or figure-maker, as figures of a certain style or character were denominated Dædala (Δαίδαλα). Pausanias (ix. 3, &c.) says "the ancients called wooden figures Dædala;" and he adds, that he thinks it likely that the artist was called after the works, rather than by his own name; thus making Dædalus a title or surname. The same author was shown some wooden statues attributed to Dædalus, which he admits were not beautiful, but he says there was in them a certain air of grandeur (ii. 4). Smilis was a native of Ægina, and the son of Euclides. He was said to be contemporary with Dædalus, and he made a statue of Juno at Samos. Endoeus was an Athenian, and a scholar of Dædalus, and, according to ancient writers, executed various important works. Pausanias (vii. 5) speaks of a colossal statue in wood of Minerva Polias, which was preserved in his time in the temple of Erythræ in Ionia. It was a seated figure. Other statues by this artist are also mentioned, executed in stone and in ivory.

A mere list of the earlier Greek sculptors can throw little light upon the state of the art; more especially when the existence of many of those whose names are handed down to modern times may fairly be questioned, at least as to the dates assigned to them; and of their skill we certainly possess no authentic examples.

About 869 B.C., Phidon of Argos is said to have struck the first money in Greece, in the island of Ægina. Some extremely rude and simple coins of that island are extant; the device is a tortoise; and from the very primitive style of execution, they are thought not to be very remote from the period alluded to. It has been supposed that the employment of metal for sculpture took place soon after the striking of money under Phidon; and about this time we find mention made of statues of brass or bronze.

Among the sculptors recorded in the annals of art is Gitiadas of Sparta, of whom there were works remaining at Lacedæmon at the time of Pausanias (lib. iii. 17). Gitiadas exercised the profession of architecture as well as sculpture. Learchus also, a sculptor of Rhegium, is placed about this date. Pausanias mentions a bronze statue of Zeus at Lacedæmon, which was said to be by Learchus, and he calls it the most ancient statue in that material known to exist. The next names of importance that occur in the history of art are Telecles, Rhœcus, and Theodorus, to whom sculpture seems to have been indebted for various and great improvements. Their reputation for skill was so high, and their innovations in the practice of art so important, that they were even called inventors of some branches of it, which, however, it is obvious must have been known long before they appeared. Such, for instance, was the case with modelling, or the plastic art, which Pliny ('Hist. Nat.', xxxv. c. 12), recording without examination all that he read, says was attributed to them; though he himself declares that this discovery was claimed by or given to Dibutades of Corinth. Rhœcus and Theodorus were born at Samos. ('Paus.', viii. 14.) There appear to have been two sculptors of the latter name; one the son of Rhœcus, the other of Telecles. Rhœcus, architect as well as statuary, is said by Herodotus (iii. 60) to have built the temple of Hera at Samos. He was also considered the author of a statue, of a female, which the Ephesians called Night. Pausanias says that he was unable to find any bronze work of Theodorus; but Pliny alludes to several by an artist of that name. Theodorus, the son of Telecles, was considered the inventor of an art which was rarely exercised by the ancients, that of casting figures in iron. According to Herodotus, Theodorus engraved the celebrated ring of Polycrates, tyrant of Samos. He is also said to have made one of two magnificent vases which were presented by Crœsus, king of Lydia, to the temple at Delphi. It has been argued from this circumstance that Theodorus must have lived at a later date than that usually assigned to him. But it is not stated that the vase was made expressly for Crœsus. It is more probable that it was among the treasures of the king, and from its age, the reputation of its maker, and its intrinsic value, might have been thought worthy of dedication. Theodorus is noticed by Pliny for a work of great delicacy and minuteness, a statue in brass of himself, holding in one hand a file, alluding probably to his profession; in the other a *quadriga*, so small that a fly might cover it with his wings. With respect to the dates of the above artists, Pliny says they lived long prior to the expulsion of the Bacchiadæ from Corinth, an event which occurred in the thirteenth Olympiad, about 659 B.C. It is conjectured, therefore, that Rhœcus, and the first and second Theodorus, lived between 800 and 700 years B.C.

The introduction of casting in metal forms an interesting epoch in the history of art, and it is to be regretted that our information with respect both to time and place, that is, the part of the country in which it was first practised by artists of Greece and Asia Minor, is so limited. The fact of Learchus of Rhegium being recorded as one of the earliest statuaries would lead to the inference that the art was known in Italy before it was adopted in Greece.

Some antiquaries place Dipœnus and Scyllis between 800 and 700 B.C., a date which Flaxman ('Lect.', p. 75. 79) adopts in speaking of these sculptors. Others supposed they lived as late as 540 B.C. They have been called the first artists who employed marble for sculpture (Plin., 'Hist. Nat.', xxxvi. 4), but it is more likely that the expression upon which this opinion has been founded means that they were eminently distinguished for their skill (which may have been extraordinary at the time) in working in that beautiful material. They were employed by the Sicyonians to make for them certain statues of their gods; but we are told that having taken some offence, they quitted Sicyon, leaving their work unfinished. The country was soon after afflicted with famine; and, upon consulting the oracle, the Sicyonians were told that it would cease when the statues of the gods were completed. Dipœnus and Scyllis were persuaded to return, and they finished the statues; they were of Apollo, Artemis, Heracles, and Athene. Among their numerous scholars we find Learchus of Rhegium, which will account for the earlier date that is assigned them. They are also called the masters of Tectæus and Angelion, Dorycidas, Dontas, Medon, and Theocles. ('Paus.', ii. 32; iii. 17, &c.) Dipœnus and Scyllis were considered the founders of the school of Corinth.

From the earlier time of which mention has been made, down to about 550 B.C., there probably was little change in the style of sculpture, although great improvement in execution or mechanical power doubtless extended the extensive practice which the growing admiration of art occasioned. In a country in which all the efforts of genius were justly appreciated, sculptors, who were called upon to represent the most exalted objects, were likely to exert themselves to the utmost to arrive at perfection; and the remains of art afford sufficient evidence that from the time alluded to, that is, between the 6th and 7th centuries before our era, when the first difficulties had been surmounted, the advancement of sculpture was rapid and uninterrupted.

It is not necessary to give a mere list of names of the artists who are supposed to have lived to this time. So much that is uncertain is mixed up with the notices of them that are found in Pliny, Pausanias, and others who refer to them, that the inquiry into their personal history would rather impede than advance our present object.

Up to the period at which we are now arrived, sculpture seems to have been practised most generally and successfully in the Greek colonies of Asia; but the consequences of the revolt against Darius, the son of Hystaspes, were utterly destructive to their further progress. Many of the temples were burnt by the Persians, and the inhabitants were carried to distant places, or were reduced to a state of slavery. But as art fell in Asia, it acquired vigour in Europe, and the artists of Ægina, Sicyon, and Corinth diffused the principles of good taste and the knowledge of art throughout neighbouring countries; a feeling for a grand style of sculpture was soon exhibited wherever any opportunity occurred for the practice of the art. It is interesting to be able to refer, in illustration of the character of the art at this time, to some undoubted remains of sculpture of a period certainly not very remote from that under consideration. These consist of eleven statues which decorated the western and five statues that stood in the eastern pediments of a temple in the island of Ægina, where they were discovered, in the year 1812, by some English and German travellers. An account of them, with a detailed notice of their style of execution, is given under ÆGINETAN ART.

The Selinuntine marbles, so called from their having been found at Selinunte, on the site of the ancient Selinus, in Sicily, are very curious examples of early art. They consist of fragments of marble alti-rilievi, and seem to have formed part of the decoration of two temples, of which traces still remain. There are some peculiarities about these sculptures which are characteristic of two different styles of art. Those which belonged to one (distinguished as the Eastern) temple, have many points of close resemblance to the style of the Archaic (Æginetan) school, while those of the western temple appear to have come either from a more barbarous hand, or to be of a much earlier date than the others. Without having the sculpture to refer to, it is difficult to explain in what these peculiarities consist, but a comparison of what remains of a head of Athene, and that of a dying or wounded warrior, with some others of the collection, will suggest the inference we have ventured to draw. The head of the dying figure closely resembles (in character) that of the warriors in the marbles of Ægina; in the other figures there is a greater resemblance to the full overcharged forms described as characteristic of the very earliest art, and approaching indeed in some degree to the works of the Egyptians. At a later period than that to which these sculptures may be referred, the artists of Ægina were invited by the tyrants of Sicily to execute works in that country. It is highly probable, therefore, that in more remote times, and when art was still less known or practised there, foreign artists should have been employed in furnishing the decoration of the temples of newly founded cities. These artists would be the most esteemed of the time, and the rising school of Ægina would doubtless take a high rank amongst them. Joined with these, or probably working under them, the natives of the country might also have contributed their ruder efforts towards the same important object, and this would sufficiently account for the difference referred to with respect to the style and treatment of the various works.

From about 500 B.C. the succession of the great sculptors of Greece, and the changes that each master and his school effected in the style of art, can be traced with tolerable accuracy. Sicyon and Ægina were the most celebrated schools of sculpture, and unrivalled for the high quality of their bronzes. After Callo, or Callon, a sculptor whose date is very uncertain, the Æginetan artists of the greatest celebrity seem to be Glaucias and Onatas. These artists were much employed by Gelon, the tyrant of Syracuse, and his successors. Onatas, the scholar of Tectæus and Angelion, enjoyed a high reputation, and, judging from the numerous works which Pausanias (lib. vi., viii. ix., x.) attributes to him, must have had very extensive employment. This writer speaks of a colossal statue in bronze of Apollo, which was at Pergamus, the work of this sculptor; likewise a statue of Ceres, which he made for the Phigalians. There were also several works of Onatas at Olympia. One was a colossal bronze figure of Heracles, placed there by the Thasians. For the people of Pheneos he executed a statue of Hermes, dedicated also at Olympia. In this work he had the assistance of Calliteles, who was his scholar, and probably his son. (Paus., v. 27.) Onatas and Calamis worked together on a chariot and accompaniments, which was dedicated at Olympia, after the death of Hiero, king of Syracuse; and in another great work described by Pausanias, we find Onatas associated with Calynthus, showing that it was not unusual, nor considered derogatory to either, to secure the talents of various artists in one work. According to the above-mentioned writer, Onatas was a painter as well as statuary. His performances spoken of in this branch of art were executed for the Platæans: one of his pictures, with a work by Polygnotus, was preserved in the temple of Athene Area. (Paus., ix. 4, 5.) Sculpture was now rapidly approaching towards the perfection which it attained under Polycletus and Phidias; and an event occurred in the 5th century before the Christian era, which tended to accelerate this progress. This was the disastrous termination of the expedition of Xerxes against Greece. The failure of this vast undertaking showed the Greeks their own strength, while it also exhibited to them the immense wealth of the invaders, and placed in their hands the means of effecting the most costly improvements and decoration. It was customary in Greece to dedicate a tenth of all spoils gained in battle to the service of the gods; and that proportion of what was obtained from the Persians was, as a matter of course, appropriated to that purpose. Its value was expended on the construction of magnificent temples, enriched with sculpture and painting, and ornamented with vases, tripods, shields suspended as trophies, and every variety of decoration. The Persians, in their invading march, had destroyed every temple that they met with; but after their retreat and disgrace, they were all restored with increased magnificence. The ample employment thus afforded for their talents, and the high purposes to which their works were destined, excited a noble spirit of emulation among the artists, whose minds seemed to expand with the greatness of the objects required of them.

The gradual improvement of style in art, from the Archaic period, and through the early Æginetan and Athenian schools, is traced by some of the ancient writers. "The works of Callon," Quinctilian says ('Orat. Instit.,' xii. 10), "with those of Hegesias, are hard, and approached what was distinguished as the Etruscan manner. Calamis was less rigid, and the style of Myron, who followed, was still more softened." In Cicero we find a still more extended list, and a confirmation of the quality of improvement down to a contemporary, as in the above instance, of Phidias, the great master of sculpture. He says that statues of Canachus were more rigid and hard than was agreeable to the truth of nature. Those of Calamis were also hard, but still they were of a softer character than those of Canachus; nor were the works of Myron close enough to nature, though there could be no doubt that they were very beautiful; but the productions of Polycletus, he adds, were still more beautiful, and were truly perfect. (Cic., 'De Clar. Orat.,' c. 18.)

The history of the progress of sculpture in Greece has now been carried through the earlier schools, into a period at which it may be considered to have reached its perfection, as far, at least, as regards the principles on which it was practised. The chief sculptors of this age were Hegias, Pythagoras, Ageladas, Myron, Polycletus, Phidias, Alcamenes, and others. Hegias, Egesias, or Hegesias, has been noticed among the sculptors of an improving class, but whose works still gave indication of belonging to the Archaic time.

Pliny distinguishes at least three statuaries of the name of Pythagoras, but although allusion is made in ancient writers to artists so called of Samos, Rhegium, and Paros, it appears probable that there were only two of very high reputation. The most celebrated was a native of Rhegium, and the scholar of, or, more correctly speaking, of the school of Clearchus. (Paus., vi. 4.) He executed, among other works, several statues of conquerors in the public games, and he eminently contributed to advance the character of sculpture by his success in giving expression to his statues. Till his time this quality, so indispensable to excellence in art, seems to have been little thought of. A work by him is particularly alluded to for its excellence in this respect: it was a figure of a lame or limping man, in which the expression of anguish was so admirably pourtrayed, that the spectators were affected, and seemed to feel the pain he was suffering. Pythagoras is also noticed as being the first who represented veins in his statues, and as having bestowed greater care upon the treatment of the hair. From these curious and interesting particulars it is easy to see in what manner the dryness and almost prescriptive character of early art was giving way to the bolder as well as more refined treatment of the Phidian age. Pythagoras may be placed about 480 B.C. He had a scholar called Sostratus. (Pliny, 'Hist. Nat.,' xxxiv. 8; Paus., vi., &c.)

Ageladas holds a distinguished rank among the sculptors of antiquity, not only from the quality and number of his works, but also from the circumstance of his having been the master of the three most eminent artists of the brightest period of sculpture, namely, Myron, Polycletus, and Phidias. He was a native of Argos. There is some reason to think that there were two sculptors of this name. Pausanias (iv., vi., vii., and x.) alludes to various statues by Ageladas. He seems chiefly to have worked in bronze.

Myron was a native of Eleutheræ, according to Pliny ('Hist. Nat.,' xxxiv. 8), or an Athenian, according to Pausanias (vi. 2, &c.). There is no artist of antiquity who is mentioned more frequently or more honourably than Myron, and it is scarcely possible to believe that such universal praise would have been accorded if his works had not fully deserved it. It is unfortunate that no known production from the hand of this distinguished artist has reached our times. The only work of which any judgment can be formed is his famous statue of a Discobolus. Various copies of this figure are believed to exist. The best is in the Palazzo Massimi in Rome. The Discobolus, in marble, in the collection of sculpture in the British Museum (see the article Discus), is also believed to be a copy from the same celebrated original. A mere list of the works of this sculptor is unnecessary in this place. The chief of them are noticed under Myron, in the Biog. Div. The peculiar characteristic of the sculpture of Myron seems to have been expression. Petronius, in spite of Pliny's assertion, leads us to believe that this was the great excellence of Myron; he says, "Myron qui pene hominum animos ferarumque ære expresserat." With respect to his style, it seems probable, from some remarks of Pliny, that his works still exhibited certain peculiarities of treatment that belonged to a ruder age, though he gives him the high praise of superiority, in some respects to Polycletus. He says he introduced more variety into his figures, for this seems to be the true interpretation of the expression of the above writer. "Primus Myron multiplicâsse varietatem videtur, numerosior in arte quàm Polycletus," &c. ('Hist. Nat.,' xxxiv. 8.) The works of Myron were chiefly executed in bronze. He used that which was made at Delos, while his rival Polycletus preferred that of Ægina. Though chiefly celebrated for his productions in this material, he worked also in marble, and a statue is mentioned by him of Hecate, made of wood. (Paus., ii. 30.) Myron had a son called Lycius, also a distinguished sculptor.

Polycletus of Sicyon was one of those who eminently contributed to ennoble art, and to carry sculpture to perfection in what has been called the sublime style. In one respect he is said to have been superior to Phidias himself; inasmuch as he was considered to have carried to perfection the *Toreutic art*, which Phidias had only, as it were, commenced. Polycletus was the author of that perfect rule of proportion called, by way of distinction, the *Canon of art*. [Polycletus, in Biog. Div.]

The name of Phidias completes, or rather crowns, this list of the great originators of the highest style of sculpture. [Phidias, in Biog. Div.] The most splendid and the most perfect productions in the art were executed by him, and as long as the principles which he taught were retained, sculpture seems truly to have merited the epithet of sublime. Phidias was called the sculptor of gods; and the majesty of his Olympian Zeus was declared, in the forcible language of an ancient writer, to have added something to the beauty or sublimity of religion. That works of art are capable of exalting the mind, and rendering it susceptible of the most pure and elevated feelings, there can be no question, and this doubtless was the effect produced by the awful grandeur of this far-famed statue. Panegyric has almost been exhausted in recording the merits of this sculptor; but there is no reason to doubt the justness of the honour paid him. Many of his finest productions were in existence when, even comparatively late writers were living, so that the accounts that have come down to us are not merely the repetitions of unsupported or unproved traditionary encomium. The statue of the Olympian Zeus was existing till the year 475 of our era. It was then destroyed by fire at Constantinople; whither it had been transported by the emperor Theodosius the First. Unfortunately no remains of the greater works of Phidias have reached our times; but we have abundant opportunity of judging of his excellence, from the sculptures which, under the title of the Elgin Marbles, form a part of our national collection of antiquities. There is no doubt that these are the productions of this great artist; many of them probably from his own hand, and all executed under his immediate direction. They formed part of the decoration of the Parthenon at Athens, of the building and enrichment of which Phidias had the entire direction. The architects Callicrates and Ictinus worked under him. These sculptures consist of the statues and groups which were placed in the pediments of the temple; of several metopes, in alto-rilievo; and of a considerable portion of the frieze of the cella, in basso-rilievo. [ELGIN MARBLES; ALTO-RILIEVO.]

The perfect acquaintance which the best sculptors of this time had with the anatomy and character of animals is worthy of remark. The skill of Myron has already been alluded to. The horses in the Elgin Marbles are admitted by competent judges to be representations of the finest shape and of the best blood. The commonest observer is struck with their spirited and at the same time graceful action. In short these works may be studied with advantage for every quality that sculpture should possess; for truth, beauty, expression, and composition, united with the purest style and most masterly execution; and they may justly be considered the finest specimens of ancient sculpture that are known to exist.

It may be as well to offer in this stage of the history of the art some observations upon the combination or mixture of materials in sculpture. The custom of using a variety of materials for the different parts of statues, as marble, or stone, or wood for the heads, hands, and feet, and metal for the draperies and accessories, was very general throughout Greece and Asia Minor from a very early period; and although it militates against the received notions of a pure taste, the practice was in full force during what has always been considered the best period of art, namely, the age of Pericles and Phidias. Nor was this mixture of materials the only interference with the simplicity which some have supposed a principle and essential quality of Greek art. The hair of marble statues appears in some instances to have been gilt, and even colour was added to heighten effect. The background of works in rilievo was frequently painted blue, remains of which may still be traced on many ancient works. (Kugler, 'Polychromie,' &c.; Millingen; Müller.)

The occasional practice of introducing eyes of silver, glass, or paste, has already been alluded to in the introductory part of this essay, in speaking incidentally of Polychromic and Polylithic sculpture. The injurious effect of this introduction of gaudy and sparkling foreign substances upon the higher qualities of any work, such as its composition and expression, seems to be beyond dispute. It may be judged of in wax figures, and in some of the richly dressed and elaborately worked and ornamental images in Roman Catholic churches, and in Hindu temples. No arguments, even when supported by the authority of ancient practice, can render such works otherwise than disagreeable as imitative art to any but vulgar minds. An artist of superior power might possibly so treat his work that its expression, the beauty and grandness of its forms, and the scale on which it is executed, might take such entire possession of the spectator as to make him overlook the incongruous mixture of materials; but it is inconceivable that, with their refined taste, extreme sensibility to beauty, and great knowledge of the essentials of art, the Greeks could ever have preferred works of this kind to those of more simple composition. The probability seems to be that the employment of ivory and gold was owing as much as anything to the desire to use the most costly materials, as all the important works so composed appear to have been executed under peculiar circumstances, either as great national contributions, votive offerings in honour of the gods, or as trophies. In the case of tenths of spoils, when vast riches had fallen into the hands of the Greeks, and were devoted to a particular purpose, it was essential to find employment for them in exclusive furtherance of that object; and as the architectural details of their temples were richly ornamented and painted, and even golden shields were suspended over the architraves and friezes, it was natural to expend a liberal portion of enrichment on the statue of the presiding divinity. This opinion receives some support from the fact that the practice seems to have been almost if not entirely discontinued as the taste for art for general purposes increased. When we read of exquisite productions by Praxiteles, in marble, or Lysippus in bronze, there is no mention of works executed at the same period in richer materials.

Sculpture in gold and ivory has been called *Chryselephantine*, from the Greek words χρυσὸς, "gold," and ἐλέφας, "ivory." It was not first introduced at the time to which our history has reached, as Pausanias describes works so composed, of a much earlier date, existing in the Heræum, or temple of Hera, at Olympia, as well as in other places; but it was during this period that it was carried to its highest point of excellence. The two most celebrated works recorded in these costly materials are the masterpieces of Phidias. They were, the statues of the Athene of the Parthenon, and that of the Olympian Zeus in his temple at Elis. The exposed parts of the figures were made of ivory, and the drapery and accessorial enrichments of gold. Of the enormous value of this kind of work some idea may be formed from the accounts of the ancients, that the figure of Athene was twenty-six cubits high, and that the gold employed on it weighed forty talents. (Plin., 'Hist. Nat..' xxxvi. 5; Thucydides, ii. 13.) One writer says there were fifty talents of gold on it. (Diod. Sic., xii. 40.)

Chryselephantine sculpture seems to have been a branch of what the ancients called *Toreutic*. The exact meaning of this term has not been satisfactorily explained. (See 'Le Jupiter Olympien,' par Quatremère de Quincy, where several opinions are collected; also 'Archäologie der Kunst,' by Müller; Millingen, 'Ancient Inedited Monuments,' &c.) It was probably used to describe sculpture in which metal, which was worked or chased, was combined with other materials. Pliny says Polycletus brought the art to perfection. ('Hist. Nat.', xxxiv. 8.)

The ancient writers do not furnish any particulars as to the mode of executing these colossal works in materials which sometimes, as in the case of ivory, could only have been supplied in comparatively small pieces. Pausanias (v. 15) tells us that an edifice called the workshop of Phidias, near to Altis, was pointed out to him. It was there, he says, that the sculptor worked each of the parts of the Olympian Zeus. In addition to the original cost of these productions, there seems to have been great care necessary to preserve them. The Olympian Zeus was surrounded by a groove or channel of black marble containing oil. The object of this was, first to supply the necessary quantity of moisture to preserve the ivory; and secondly, to secure the work from damp, as the Altis was situated on marshy ground. Means were also adopted at Athens for preventing injury to the ivory parts of the Athene, from the too dry situation of the Acropolis. We are told that the statue of the Olympian Zeus was out of repair very soon after its completion; and the fact of the Phædruntæ being established to take care of the work, is a proof of its liability to accident. Pausanias mentions a remarkable circumstance connected with the persons appointed to this duty. It had been entrusted to the descendants of Phidias, and he says that it was in the same family in his time.

The scholars and followers of Phidias were Agoracritus of Paros, Alcamenes of Athens, Colotes or Colotas, Pæonius, and others. The first two deserve notice for the celebrity of their names and works. Agoracritus was the favourite scholar; Alcamenes, judging from the accounts left of him, the most able artist. He was considered second only to his great master; and one author, alluding to the progress made in sculpture, even classes him with Phidias, saying, that what was wanting in Polycletus was to be found in the works of Phidias and Alcamenes. (Quinctilian, lib. xii., 10.)

The sculptures of Phigalia, consisting of a series of alti-rilievi, representing the battle of the Lapithæ and Centaurs, and of the Greeks and Amazons, are of this age. The temple of which they formed part of the interior decoration was built by Ictinus, the architect, under Phidias, of the Parthenon; and from the style which pervades them, there is every reason to think these compositions proceeded from the same source as the sculptured portions of that edifice. The inferiority of their execution may be easily accounted for by supposing the working out of the designs of the master to have been left to the scholars or inferior artists. These interesting remains have already been more particularly described. [PHIGALIAN MARBLES.] The original sculptures are preserved in the British Museum.

The influence of Phidias continued to be felt for some time. Art had gradually been relieved from the dryness and hardness of the Æginetan school, and Phidias produced out of it the grand character which marks his period; but it appears there was still remaining a severity both in the forms and in the treatment, in the works of some of the artists of this school, which it was left for a sculptor of a succeeding age to remove. This change, which stamped the character of a new school of sculpture, was effected by Praxiteles.

When the restrictions which originally confined sculpture to religious purposes and prescribed forms had once been disregarded, and the art was applied to represent objects of general beauty and interest, it rapidly underwent changes; and the sculptors of the period which we are now considering, that is, at about 350 B.C., succeeded in introducing an entirely new quality of art. The grand, the sublime, and the severe, gave way to the soft, the flowing, and the graceful. At the head of these innovators was Praxiteles. He worked in bronze and in marble; but his most beautiful and admired performances were probably in the latter material, in the working of which he exhibited the greatest skill, and in which he is said to have introduced processes unknown to his predecessors. [PRAXITELES, in BIOG. DIV.] He is supposed to be the first sculptor who ventured to make a statue of Aphrodite entirely naked: all statues of female divinities were anciently draped. (Millingen, 'Monuments,' x. p. 7.) Such an innovation was considered extremely indecorous; but it was excused in this instance, on account of the beauty of the performance. Subsequent artists, desiring to reconcile a mode of representation so favourable to the purposes of art, with the prejudices still existing in a degree in matters pertaining to religious personages, seem to have adopted a middle course, as is seen in the two statues of Venus called of Capua and of Melos. ('Museo Borbonico;' 'Galérie du Louvre.') In these the forms are left entirely naked down to the middle, from whence rich drapery falls to the ground, covering all the lower portion of the figures.

The next name of importance, as the leader of a new school, is that of Lysippus of Sicyon. The reputation of this artist is not inferior to that of any sculptor who preceded him. He appears to have worked exclusively in bronze; and, according to Pliny, executed as many as six hundred and ten works. [LYSIPPUS, in BIOG. DIV.] A colossal statue at Tarentum by him is much distinguished. Lysippus was the favourite sculptor of Alexander the Great, and had the exclusive privilege of making statues of him. A long list of works by Lysippus is furnished by Pliny, Pausanias, and other writers. He is said to have paid great attention to the treatment of hair, and to have introduced an improvement in proportion, making the heads of his figures smaller than his predecessors had done. He doubtless observed that his figures gained in elegance and effect by taking this liberty; for a saying of his is recorded, "They (the older sculptors) made men as they were; he represented them as they appeared to be." This seems to be a paradox; but it is not so, and its meaning and the value of the principle are quite intelligible to artists. It shows that Lysippus considered that very minute detail and close mechanical copying should be made subservient to general effect. Lysippus left several scholars, three of whom, his sons Daippus or Laippus, Bedas, and Euthycrates, are mentioned amongst the most eminent of his successors. The last is said to have imitated the firmness, or the austerer parts, of his father's practice, rather than his more elegant and pleasing qualities. "Therefore," says Pliny ('Hist. Nat.,' xxxiv. 8), "he succeeded admirably in a statue of Hercules at Delphi," &c. There is a fine bronze statue of Hercules in the Townley Gallery in the British Museum, which has every indication of being of this school.

The perfection of sculpture seems to have been attained under Praxiteles and Lysippus. They were contemporary, and each effected in his way what was before wanting to its completion. It is believed that there are imitations of some of the works of Praxiteles in the various modern collections of sculpture. Among these are the Sleeping Faun, at Munich; the Cupid of the Vatican, at Rome; statues of Venus, believed to be copies of the far-famed Venus of Cnidus; and the Apollo Sauroctonus, at Rome.

The death of Alexander the Great (324 B.C.) was followed by the dismemberment of his vast empire. The arts suffered in some measure by these divisions and contentions; but it is difficult to assent to Winckelman's opinion, that after the death of that prince there was nothing left except a class of mere imitators. Each of the artists above mentioned left numerous scholars, who still preserved the high character of sculpture by their own successful practice. Among the most distinguished of these sculptors are Cephisodotus and Eubulus, the sons of Praxiteles; Pamphilus, his scholar; the before-mentioned Daippus, Bedas, and Euthycrates, the sons, and Tisicrates, the scholar, of Lysippus (the works of the latter are said to have been so excellent that they were often mistaken for those of Lysippus himself); Xenocrates, who also wrote a treatise on his art; Chares, the Lyndian, the author of the famous Colossus of Rhodes; Dameas, Eutychydes, and Phœnix. Hermocles of Rhodes is mentioned as having been employed by the earlier Seleucidæ. Isigonus, Pyromachus, and Stratonicus illustrated by their art the victories of Attalus and Eumenes over the Gauls; and the Ptolemies also for a time were protectors and patrons of artists. To the above names many others might be added, sufficient both in number and talent to warrant the belief that sculpture was not only still encouraged and practised on the best principles, but that there were artists living quite capable of aiding its progress by their own genius. The assertion therefore of Pliny (xxxiv. 8), that from the 120th to the 155th Olympiad the art was almost extinct, seems utterly groundless. To this or about this period antiquaries have attributed some of the most interesting remains of ancient sculpture that have reached our times. Amongst these may be noticed the well-known statue of the Hermaphrodite, at Paris; the fine fragment called the Torso of the Belvedere, at Rome; the Hercules, called the Farnese, at Naples; and the statue called the Fighting Gladiator. To these some have added the group called the Toro Farnese, at Naples, representing Dirce, Zethus, and Amphion with the bull, and even the group of Laocoon and his sons.

The fatal blow to the existence of the arts in Greece was given by the success of the Roman arms. Lucius Mummius had been sent by the senate against the Achæans. He engaged the Greek army near Corinth, the principal city of the famous Achæan League, and completely defeated it. The city was immediately devoted to destruction, and sacked by the conquerors. The Romans carried away from this celebrated seat of the arts, as well as from the other cities of Greece which fell into their hands, the greater part of the fine productions both in painting and sculpture, which had been accumulated for centuries. These were forthwith transported as spoil to Rome, which became filled, for the first time, with the most splendid monuments of Grecian taste and genius. This event occurred in the 158th Olympiad, or 146 B.C. Athens, which may be considered as the great centre of art, and the favourite asylum of the most distinguished artists of Greece, had suffered a variety of fortune since the time of Pericles, when her glory may be said to have been at its zenith. Her political importance declined from about that period, but she still seems to have maintained a character as the abode of literature and of art long after her political influence was at an end. At length she was doomed to share, in full, the calamities and humiliations to which other Grecian cities had been subjected by the victories of the Romans. Having vainly endeavoured to impede the progress of the Roman army into Greece, Athens had to submit to what she might fairly consider a barbarian conqueror. In the year 86 B.C. she received as her master the haughty and unrelenting Sulla. The history of ancient sculpture in Greece may be said to close at this time. After the establishment of the Roman empire, the Greeks no longer had either the higher inducements or the means to carry on the exercise of the arts in what may be considered their native country; and their professors were driven to seek employment and an asylum among their conquerors.

The greatest influx of Greek artists into Italy occurred when Augustus had obtained the sovereignty, though earlier than this period there had been some efforts made by individual Romans to introduce a taste for art among their countrymen. A slight general view of what had been effected in this respect, or rather, of the means used to effect this end, will not be out of place here, as introductory to the examination of what has been called Roman sculpture; but the art never appears to have been naturalised among this people, and, as will be seen, it was always rather an exotic in Rome, nursed and tended by its own natural cultivators, Greek sculptors, than a growth brought to any perfection by the people in whose stranger soil it had accidentally, and almost forcibly, been planted.

Roman Sculpture.—It is not easy to determine when the Romans began to pay attention to the arts of painting and sculpture. For a long period they were too much occupied in insuring their safety and strengthening and extending their state, to think of arts which they could then only have looked upon as unworthy of a warlike people. Their first public monuments were doubtless trophies. The trunk of a tree, stripped of its branches, and bearing the arms of the vanquished, proclaimed the achievement of the victor, and at the same time incited the young Roman to exertion in his country's cause. The sculpture mentioned as existing in Rome at a very early date was, there can be no doubt, of foreign growth, the production of their neighbours the Etrurians; and the celebrated she-wolf still existing in the Capitol, one of the most ancient and interesting monuments, whether considered historically, or as an example of early bronze sculpture, may fairly be attributed to that people.

It is recorded that after the victories of Camillus and Mænius over the Latins, equestrian statues were erected in Rome in their honour. This was above 350 years before our era, or about 400 years after the building of Rome. In the 3rd century B.C. one of the Fabii devoted himself to the arts, and acquired, from his success, the surname of Pictor. Pliny ('Hist. Nat.,' xxxv. 4) says that he decorated with his paintings the temple of the goddess of Health at Rome, and that the pictures existed in his time. A bronze statue of Apollo, made out of spoils taken from the Samnites, is said to have been dedicated in the Capitol about this period. After the conquest of Syracuse by Marcellus, Rome became enriched with the spoils which fell into the hands of the victors. The reply of Marcellus, when he was accused of rapacity for stripping the conquered city of its works of art, is remarkable: he declared he had done it in order that the public edifices of Rome might be ornamented, and also to introduce among his countrymen a taste for the arts and elegance for which the Greeks were so distinguished. The power and greatness of Rome were now being extended in all directions; and, by some caprice of fancy, generated probably by the facilities that were offered for its gratification, it became a rage to collect specimens of sculpture. Notwithstanding the opportunities thus offered for acquiring some knowledge of the beauties of art, from the mere habit of having the most exquisite examples of sculpture brought before them, it does not appear that any decided taste discovered itself till about 86 years B.C. Sulla, in his victorious march through Greece, destroyed several of the most magnificent temples and monuments of that country; but he also collected a great quantity of spoil, which he forwarded to Rome, and which consisted chiefly of the fine works which were preserved in the temples or adorned the public places. This enormous accumulation of such objects seems at length to have aroused in the Romans some feeling of admiration favourable to the existence, at least, of art in their own country. The fashion, or rather passion, to form collections at any price increased. Verres is handed down to posterity among the most zealous and at the same time the most lawless of dilettanti; but the character of the works he possessed, several of which are mentioned by Cicero in his celebrated orations against the rapacious prætor of Sicily, gives him a claim to be considered fully capable of appreciating excellence in art. The means that he adopted for gratifying his taste merit the severest condemnation; but he probably preserved from neglect and destruction many of the most valuable monuments of sculpture.

In the last century before Christ various sculptors of distinguished name were resident in Rome, or were practising their art in other parts of Italy. Among these may particularly be mentioned Pasiteles, Arcesilas or Arcesilaus, the author of a group of boys with a lioness; Saurus and Batrachus, Strongylion, Olympiosthenes, and Evander. Arcesilaus was much employed by Lucullus. Strongylion is honourably mentioned for a fine statue of an Amazon, so beautifully formed in the legs that it was called Eucnemos. He also made some statues of Muses; and Pausanias, who alludes to them, adds he was most skilful in his representations of animals. Olympiosthenes also executed three Muses. Pliny speaks in the highest terms of the merit of Pasiteles. He became a Roman citizen, and among his works is mentioned a statue of Jupiter, of ivory, which was placed in the temple (*æde*) of Metullus. It is to be regretted that a literary work of this artist, mentioned by Pliny, no longer exists. He says, "Pasiteles wrote five volumes containing descriptions of the most remarkable works in the whole world." Such a record from an artist of the character of Pasiteles would be a treasure.

Among other fine works in sculpture which are supposed to have been produced in the earlier part of this period, may particularly be mentioned the statue known as the Germanicus of the Louvre. It doubtless is intended for a figure of a Roman: but it seems to be agreed that it cannot be a portrait of the prince whose name it bears, but is of an earlier date. On the pedestal, immediately under the falling folds of the drapery, is a tortoise. As this animal was sacred to Mercury, the god of eloquence, Visconti conjectured that the statue might represent some distinguished Roman orator. A Greek inscription declares it to be the work of Cleomenes, the son of Cleomenes the Athenian; a name distinguished among those who illustrated Greece during the prosperous times of sculpture. The names of Apollonius of Athens, and of Glycon, also an Athenian (the sculptors, according to the inscriptions on the works, of the celebrated Torso and of the (Farnese) Hercules), do not occur in Pausanias; which has occasioned a doubt whether they had executed many works remaining in Greece in the time of that writer. They are thought to have lived in the century before our æra.

Julius Cæsar gratified his taste for the fine arts by collecting statues, gems, and similar objects. His patronage extended itself even to remote places, and he not only embellished Rome, but many cities of Gaul, Spain, Greece, and Asia Minor participated in the advantages of his good taste.

A great impulse was given to the encouragement of sculpture by Augustus. He caused all the finest works that could be procured to be collected, and he had them placed in the public places of Rome. He is also said to have removed the statues of illustrious men from the area of the Capitol to the Campus Martius. (Suet., 'Calig.,' 34.) The example of Augustus was imitated by the wealthy Romans, and no expense was spared in adding new and admired productions to the different collections of statues and paintings. Among the most liberal of the patrons of this period, Agrippa stands pre-eminent for the munificence with which he devoted his fortune to the embellishment of Rome. The Pantheon is a monument of the taste and princely liberality of a Roman citizen. Agrippa employed an Athenian sculptor, called Diogenes, to enrich this temple. Pliny particularly alludes to some Caryatides by him, as well as to some figures in the pediment or front (*fastigio*); but these Pliny ('Hist. Nat.,' xxxvi. 4) says produced less effect, owing to the height at which they were placed. It is recorded that Agrippa constructed some aqueducts, which he decorated with three hundred statues in bronze and marble. During the age of Augustus the names of many very distinguished artists occur. Among them, Vitruvius, the architect, Posidonius, a native of Ephesus, and the celebrated Dioscorides, the engraver of gems, may be particularly mentioned.

The good effect of the example of Augustus seems to have been long felt in Rome, though it does not appear that Tiberius contributed much to preserve or nourish a taste for art. A circumstance however is said to have occurred during this latter reign which shows that the Romans were alive to the value of fine public works. Tiberius admired a statue representing an athlete anointing his limbs, by Lysippus, which stood in the baths of Agrippa—a place, it seems, of public resort. Desiring to have exclusive possession of this work, he had it removed to his own palace; but the dissatisfaction of the people was so great, and their indignation at the emperor's depriving them of what they considered public property so violently expressed, that Tiberius, fearing a revolt, ordered the favourite statue to be replaced in its original situation.

Caligula had works of art brought to Rome from Greece, but it does not appear that he had any admiration of them as objects of beauty or as memorials of an enlightened people, but rather that he considered them as means of gratifying his personal vanity. He ordered the heads of the gods and of illustrious men to be struck off their statues, and his own to be substituted. This paltry ambition, which could be exercised at a cheap rate, accounts for the mutilation of many statues that have reached our times, and in which a totally different character will often be observed in the heads and other portions of the work. Caligula is recorded as the first emperor who was guilty of this species of sacrilege; but he appears to have been imitated by many of his successors. It is a curious fact that, notwithstanding the efforts so unworthily made by Caligula to make himself known to posterity, portraits or busts of this emperor are extremely rare. The reigns of Claudius and of Nero at first gave promise of encouragement to the arts; the latter emperor required decoration for his Golden Palace, which he constructed on the Palatine Hill; and although the vast number of works that had already been procured from Greece would seem to have robbed that country of all its treasures, he procured no fewer than five hundred bronze statues from the temple of Apollo at Delphi. Two of the best works of ancient sculpture, the Apollo Belvedere and the so-called Fighting Gladiator, were found among the ruins of a villa or palace of Nero at Antium. Zenodorus the sculptor was employed by Nero to make a colossal statue of him, of bronze, a hundred and ten or a hundred and twenty feet high. (Plin., 'Hist. Nat.,' xxxiv. 18; Suet., 'Ner.,' 31.) Zenodorus was called to Rome from Cisalpine Gaul, where he had executed a colossal statue of Mercury, a work which had occupied him ten years. Menodorus, an Athenian sculptor, lived at this time. His statues of athletæ, and subjects of that class, are mentioned in terms of commendation. It is probable that there were two artists of this name.

This may be considered the period at which the introduction of variously coloured marbles in statues became the fashion in Rome. The Roman *polylithic* sculpture differed in some respects from that practised by the Greeks. The Roman mode was to imitate the different stuffs of which real draperies were composed, as well as the ornamental dressings of the figures, with marbles (usually Orienta alabasters, &c.) closely resembling them in colour. The Greeks occasionally used different materials, not often marbles, for this purpose; but not with the intention of imitating the particular colour or texture of the object represented. The Romans carried this so far as to express, in white and dark marble, the colours of the eyes in a statue, in black marble, of an Ethiopian. More than one example of this may be seen in the various collections of ancient statues. The reigns of Otho, Galba, and Vitellius were too short and too disturbed to give those emperors time or opportunity to encourage sculpture. Otho ordered a large sum, ninety millions of sesterces, to be appropriated for the completion of the Golden Palace of Nero. Busts of these emperors are extremely rare. There is one of Vitellius in the Museum of the Louvre, of very high merit; but most of the portraits of this prince have been considered modern.

Vespasian, Titus, and Domitian encouraged sculpture. Titus erected two statues, one of gold, the other equestrian, of ivory, in honour of Britannicus, the son of Claudius, who was poisoned by Nero. (Suet., 'Tit.,' 2.) Statues of Domitian are rare, in consequence of the order issued by the senate, after the tyrant's death, that all statues of him should be destroyed.

But little now occurs in the history of sculpture worthy of notice till the time of Trajan. The taste and energy of this prince reanimated the arts both in Greece and Italy. Zeno of Aphrodisias was a sculptor of this time. The column of Trajan is an interesting monument of the art in the latter part of the 1st century after Christ. The reigns of Trajan, Hadrian, and the Antonines may justly be accounted the golden age of sculpture in Rome; though even then it is probable that the art was little practised by native artists. In Hadrian especially the arts found a munificent protector. He restored many of the ancient temples which were falling to decay; he erected others in a style worthy of the best ages of the art; and, among other public-spirited undertakings, completed the temple of the Olympian Zeus at Athens. Among the enrichments bestowed upon it was a statue of Zeus in gold and ivory, several other works placed there by Hadrian, and finally a colossal statue of the emperor himself. The scale of magnificence in which this prince indulged may be estimated from the remains of his celebrated villa near Tivoli, about eighteen miles from Rome. It was embellished with all the finest works that could be procured, whether the productions of ancient Greek artists or of those of his own time. Some of the most interesting and valuable remains of antiquity have been discovered there; and even at the present day every fresh excavation that is made among these ruins restores to the world some object of interest. Some of the Egyptian superstitions having been introduced into Italy about this time, they were mixed up with the existing forms of worship, and the gods of the Nile were admitted among those of the Romans. The example of the capital was soon followed by the smaller communities; and, as the new worship was extended over the whole empire, a great demand arose for statues, and other symbols of Egyptian deities and ceremonies. The imitations of Egyptian figures and subjects which are found in Italy, and which particularly abounded among the ruins of Hadrian's villa, may be assigned to this period.

The numerous specimens of sculpture of the time of Hadrian that are preserved in modern collections are evidence of the high state of the art. The statues and busts of himself, and of the emperors who immediately preceded and followed him, as well as the portraits of Antoninus and Lucius Verus, exhibit qualities that would do honour to the best ages of Greek sculpture. There are two statues of Antinous in the museum of the Capitol, one treated in the Greek style, entirely naked, and the other with Egyptian attributes, which are particularly worthy of notice for the simplicity and beauty united with grandeur that pervades them. They carry us back to the very finest period of the practice of the art.

Sculpture declined after the death of Hadrian. The difference observable, both in style and execution, in the two columns of Trajan and Antoninus, exhibit a marked change in the condition of art, even in the short period that elapsed between the execution of these works. Antoninus Pius was not, however, neglectful of art; but the chief employment of that time seems to have been in portraits and busts, a sure indication of indifference towards the higher class of design.

Herodes Atticus claims a distinguished place in the list of promoters of the fine arts. He employed his immense wealth in embellishing Athens and other cities of Greece. Chryselephantine sculpture was still practised; for it is recorded that he caused a quadriga, with a group of Neptune and Amphitrite, made of gold and ivory, to be placed in a temple of Corinth. By the time of Septimius Severus (about A.D. 200) the arts of design had rapidly declined. The schools for their cultivation, which had been established by Hadrian, were no longer kept up, and the effect of the neglect of pure design is visible in the monuments of this period. The sculpture on the arch of Sept. Severus, in the Forum of Rome, as well as that called the Arch of the Goldsmiths, also at Rome, offer undeniable evidence of the low condition of taste, and the inferiority of practice in art. Considerable care was shown in the littlenesses of execution; but everything that indicated boldness of conception, breadth of treatment, and style, had vanished. With the exception of busts, some of which must be admitted to have great merit, the monuments which remain of the time of Caracalla, Geta, Alexander Severus, and their successors, only confirm the rapid fall of sculpture. Alexander Severus endeavoured to revive a taste for architecture, and even instituted schools for the education of students; but the calamities that disturbed Italy during the contentions for the empire, left men little leisure for elegant pursuits. The degraded state of sculpture in the 3rd century of our era is sufficiently declared by the quality of the bassi-rilievi on the arch of Constantine in Rome; all that were not taken from the arch erected in honour of Trajan's victory over the Dacians, exhibit the utmost poverty of design, with feebleness of execution.

The dismemberment of the Roman empire by the establishment of a seat of imperial government at Constantinople, was a fatal blow to the grandeur and magnificence of Rome; and from this time may be dated the downfall of the city. To Constantine himself some honour is however due for his endeavours to restore a feeling for the arts, by the scale on which he proposed to decorate the new imperial residence. Sensible of the want of artists capable of doing justice to his splendid conceptions, he instituted schools, especially for architecture; and by distributing rewards and giving privileges to students, he endeavoured to induce young men to devote themselves to acquiring a knowledge of the art. He so far succeeded that several considerable buildings were erected, but they were indebted for their decoration to the sculptors of a past age. By the emperor's commands, the cities of Greece and Asia Minor were despoiled of what had been left them by preceding collectors. Statues of gods, heroes, sages, and poets were brought together from all parts, to contribute to the splendour of the new city, and nothing, Cedrenus observes, seemed wanting, but the souls of the illustrious individuals whom these admirable monuments were intended to represent. Some attempts were made to restore sculpture by giving employment to contemporary artists; and statues in metal were erected in this reign and in the subsequent reigns of Constantius, Theodosius, and Honorius; but the spirit of ancient art was lost, and these works, of a totally distinct character from that of the finer Greek schools, appear to have had so little merit, that the names of their authors have not been recorded.

The state of Italy in the 5th and 6th centuries rendered the restoration of the fine arts utterly hopeless. During this unhappy period of her history she suffered from the inroads of the northern nations. In the year 412, Alaric, king of the Goths, ravaged the country and gained possession of Rome. At a later period the city was given up to pillage by Odoacer; and Genseric and his Vandals subsequently added to the destruction. In 545 Rome was attacked by the Goths under Totila; they set fire to the city, which continued burning for several days. In this siege, the Romans, driven to their last hold, defended themselves from the Mausoleum of Hadrian (now the Castle of St. Angelo); and, we are told, threw down upon their enemies the statues which decorated that sumptuous edifice. To the losses occasioned by these and similar means are to be added those consequent upon the anti-pagan zeal of some of the early Christians. They used to drag down the statues of the divinities of the Greek and Roman mythology, and pound them to dust. The finest productions of the greatest masters of sculpture were thus demolished; and so sweeping had been the destruction, that when Arcadius and Honorius issued fresh edicts for carrying on the work of demolition, it was said, "Si qua etiam nunc in templis fanisque consistunt" ("If indeed there should be any still left in the temples").

The greatest treasures of art were preserved at Constantinople, and the palace of the Lausi boasted one of the finest collections of ancient statues. An immense number of these fell a prey to the flames in 479. In the year 661, Constans was driven from Constantinople by the infuriated people, and passed over into Italy. He visited Rome, where he remained a few days, but in this time he despoiled it, as far as he could, of whatever it still possessed of value in art. These works, chiefly in bronze, were carried by his orders to Syracuse, where he proposed to establish himself, and where he died.

The public attention both in the Eastern and Western empire was now too fully occupied with intestine troubles and the attacks of external enemies, to be able to think of the arts. The fury of the Iconoclasts and the conquests of the barbarians forwarded the work of destruction, and though Theodoric, and afterwards Charlemagne, attempted to stop the ravages which were consequent upon the success of their followers, and to afford some protection to the remains of antiquity, their influence was quite inadequate to effect their object or to save the monuments of genius from the violence of an uncivilised and ill-disciplined soldiery. Theodoric (about 500 A.D.) laments, in a letter to Symmachus, the ruin of works of genius, and observes that Rome still possessed a population of statues. Charlemagne formed the plan of renovating art, and most probably would have accomplished his object, if the age had been worthy of the emperor. His great purpose however was to obliterate the remembrance of the splendour of paganism by the magnificence of Christian art; and the entirely new feeling introduced occasioned a totally new style of design, which, as it has little connection with our present subject, will be considered in another place.

The Empire of the West and the glory of the Roman name had passed away. The resuscitation of art and science belongs to another period of our history.

In the 12th century Constantinople, after a series of distresses and difficulties, was taken possession of by the victorious Latins and their allies under Boniface and Baldwin; and the city, which had already been nearly destroyed by a succession of fires, was given over to pillage. Nicetas Choniates has described some of the fine remains of art that were there in his time, and which, during this reign of plunder, were broken or melted down to be coined into money, or sold for the value of the metal. Among them we find various bronze statues of charioteers that stood in the Hippodrome; a group of Bellerophon and Pegasus; Paris presenting the apple to Aphrodite; an exquisite statue of Helen; a colossal Heracles, by Lysippus; and the celebrated colossal statue of Hera, which had once adorned her temple at Samos.

The real history of ancient sculpture may be said to have ended even before the period to which it has here been carried. It is both unsatisfactory and painful to attempt to trace it farther, when each step taken only shows ruin and devastation. The monuments of the Romans are numerous, and have been useful in illustrating ancient writings and in making us acquainted with the manners and customs of that people; but Roman sculpture has not the same claim upon our attention as that of the Greeks. Indeed in following the history of the art in Italy it is obvious that the interest is chiefly kept up by considering sculpture in Rome as a continuation of that of Greece, and not as an art which the Italians cultivated with any original feeling. The best works produced were by Greek artists; and the attempts of the Romans are characterised, if it can be called character, by poverty of invention, meanness of design, and for the most part unskilful execution. The art was seldom patronised but when it was required to flatter the pride or please the vanity of individuals by portrait statues or busts; and consequently it never rose to that excellence or elevation which it attained in Greece, where it was made the means of embodying the grand conceptions of genius by the union of expression and sentiment with the most beautiful forms.

Revival of Sculpture.—After the subjugation of the Greek and the division of the Roman empire, the fine arts gradually declined. Occasionally efforts were made to revive them, but as these arose from individual feeling, and were not supported by any general interest in the subject, the attempt had little success. Charlemagne endeavoured to restore them; but his edicts, unresponded to by the sympathy of those about him, were unable to effect his object. Still the arts were kept alive by the monks of the early Greek and Latin churches, who, with pious diligence, illuminated manuscripts, and sometimes even decorated the walls of their chapels and convents with rude paintings.

It has been usual to date the revival of art in Italy at about the 10th or 11th century. The beginning of modern art may however be reckoned from an earlier time; rather, as Flaxman says, from the reign of Constantine, seven centuries earlier, when Christianity became the religion of the empire. Painting and sculpture then ceased to be employed, as heretofore, on the pagan gods, but were engaged to illustrate subjects connected with Christian worship. Even during the reigns of those emperors by whom the Christians were most persecuted, they ornamented their subterraneous retreats with sacred portraits and subjects from Scripture. (Flaxman's 'Lectures on Sculpture.') The artists to whom the chief merit of reviving art is due, are supposed to have derived no small benefit from the study of the remains of ancient sculpture which were still scattered about Italy, and particularly in Pisa, the native city of the presumed founder of the first school of modern sculpture. Without denying this very probable effect of superior works upon minds just awakening to the beauties of art, it may be disputed whether its influence was so great as some have imagined. It scarcely can be traced where it might most reasonably be supposed to exist, namely, in any peculiarities or finer qualities of style or execution; and it surely must be conceded that the mind and spirit that are observable in the paintings and sculptures of the time of the revival are of an entirely original character and quite independent of the ancient schools. This is remarkable in a class of design which at first seems peculiarly calculated to tempt modern artists to recur to the manner of the ancients, namely, that in which symbols and allegorical figures are employed. In the examples that exist by one of the earliest painters, Giotto di Bondone (chiefly in the Capella dell' Annunziata and in the Salone at Padua), there certainly is no apparent imitation of any of the numerous and varied modes of treating such subjects that were offered to him in the monuments of antiquity. Without the most remote idea of underrating the excellence of fine ancient models, it seems only just to assert a claim for the distinct and original character which divides modern Christian art from that of the Greek schools. A depth of thought, an intention pervades the Christian art, which show an entirely altered feeling; and, after the first period of the rude and almost frightful attempts at design (usually in single figures, gaunt and staring images of the Apostles and saints), the revivers of art seem to have aimed at appealing to the sympathies, rather than gratifying the eye and pleasing the fancy only, by presenting to them beautiful forms. On this ground the artists of this age were essentially men of genius; for, instead of servilely copying, they drew from their own original sources; and the art that proceeded from them eventually became, as was the case with Greek art while master-spirits directed it, great and admirable.

Passing over the performances of the artists who were employed in different parts of Italy in the century before his appearance, Niccolo Pisano may be considered the father of modern sculpture. Many of the artists alluded to united, as was usual in those days, the three professions of painting, sculpture, and architecture, and their works are interesting monuments of their ingenuity; but sculpture only assumed a distinct and appropriate character when the two Pisani, Niccolo and his son Giovanni, devoted themselves to it, and by their talents diffused a love of art throughout Italy. The cathedrals of Pisa, Pistoja, Siena, and Orvieto are rich in the productions of the Pisani. They consist of magnificent marble pulpits enriched with bassi-rilievi and statues, and are evidence of great power both in composition and in deep feeling. An account of these artists and their principal works will be found under Niccola di Pisa, in the Biog Div.

One of the most masterly compositions of any school of sculpture is a semicircular basso-rilievo, in marble, of Niccolo Pisano, representing the 'Taking down from the Cross,' which is placed over one of the side doors in front of the Duomo of Lucca. Another remarkable work of Niccolo Pisano is a basso-rilievo representing the Last Judgment and Punishment of the Wicked, in the cathedral at Siena. His power seems to have been in treating gentle, delicate, or touching representations; but the performance alluded to has great merit for the boldness of the conception, the eager crowding or fearful shrinking of the figures, and for the masterly composition. Niccolo Pisano commenced his profession early in 1200. He lived to an advanced age, and was succeeded by his son Giovanni di Pisa, Arnolfo of Florence, and other scholars. Giovanni executed some esteemed works, but in natural genius he was inferior to his father, and he was satisfied rather to imitate what had been done than desirous or able to advance the art. Sculpture did not make that progress after the death of Niccolo that might have been expected from the merit of his works and the fine opening he had made for its improvement. Arnolfo was much employed both as an architect and sculptor. Two of his works in the latter art, the monument of Boniface and the Tabernacle in the church of St. Paul (fuore le mura), are preserved in Rome. The date of their execution is about 1300, or rather later. Among the more successful imitators of Niccolo Pisano may be noticed Margaritone d'Arezzo, Guido da Como, and "Maestro" Buono.

In the year 1330, Andrea Pisano, the son of Ugolino, who was settled in Florence, executed one of the bronze gates of the Baptistery in that city. The sculpture illustrates the life of St. John. This work is admirable for its beautiful sentiment and simplicity, though it must be allowed to be deficient in the mechanical excellences of sculpture. Andrea Orcagna, contemporary with Andrea Pisano, was an architect, painter, sculptor, and poet. [Orcagna, in Biog. Div.] His works in sculpture, notwithstanding a certain dry quality of execution that pervades them, have great merit. His most esteemed performances are the sculptures on the altar in the chapel or oratory of Or San Michele, in Florence. Orcagna showed great talent in the management of his draperies, preserving considerable breadth in the forms and disposition of the folds, and so composing them as not to conceal the action of the limbs. There are some curious monuments of this early period at Naples, where sculpture was practised by the followers and imitators of Niccolo and Giovanni Pisani. The Neapolitans pretend, indeed, to cite names of sculptors even earlier than the Pisani; and mention is made of "Maestro" Fiorenza and Agnolo Cosentino of as early a date as the 9th and 10th centuries. Approaching, however, nearer to the time under consideration, we find the name of Pietro da Stefani mentioned as a respectable sculptor at Naples. His works are particularly commended for expression, a quality of difficult attainment in what may truly be considered the infancy of art. The two Masucci are also recorded among the sculptors who were at that time decorating Naples with their works. The chief occupation for the artists was in "Depositi," or tombs, monumental sculptures, and occasionally enrichments, in reliefs and small figures, on altars. The monuments were often of a very elaborate kind, uniting sculpture with architecture. Stories of figures in niches, or mixed up with Arabesque or Gothic ornaments, rose one above the other, till, at a certain elevation, the work took a pyramidal form, the apex of which was surmounted by a statue either of the Madonna and Child, or of a patron saint, or sometimes by an equestrian figure of the deceased. There are some very curious specimens of these compositions in many parts of Italy; one of the most remarkable is at Naples, in the church of S. Giovanni dei Carbonari.

The works of Luca della Robbia abound in Italy. They possess merit not only as works of art, but as specimens of a manufacture, or rather, a process, of which this sculptor is said to be the inventor and exclusive possessor. This was the art of covering *terra-cotta* models with a beautiful and peculiar coloured varnish, which renders them as hard as stone. He is supposed never to have disclosed this secret; but there is a tradition that he committed it to writing, and inclosed the paper, or whatever it was inscribed on, in some one of his models, before he sent it to be baked; so that it could only be known at the price of destroying, or at least injuring, a number of his works, till the document should appear. Among his productions are some of great beauty. They consist chiefly of groups, in alto-rilievo, of the Madonna and infant Saviour, or Christ and St. John as children, and similar subjects. Luca della Robbia died in 1442.

In the Gallery of Sculpture at Florence are preserved some extremely interesting specimens of art of this period, by Benedetto da Rovezzano and others. These works merit a careful examination, as they offer not merely valuable illustration of the progress that was being made in the art at the time they were executed, but they possess qualities which claim for them high praise as examples of rich composition and appropriate expression. Many of them are likewise worthy of attention for an approach to great beauty of form, and for the skilful treatment of the draperies.

The next distinguished names which occur in the annals of restored sculpture are those of Lorenzo Ghiberti and Donato di Betto Bardi, better known as Donatello. Ghiberti has secured a lasting reputation by his celebrated bronze gates of the Baptistery of Florence, the edifice on which so many preceding sculptors had been employed. The first gates mentioned by historians were executed by Buonano in 1180: they were destroyed by fire. Andrea Pisano was the next artist employed upon them, and his and the later works at that edifice are fortunately still preserved. The contribution of Lorenzo is in a series of rilievi, ranged in compartments, illustrating subjects from the Old Testament. Michel Angelo is said to have admired them so highly that he declared they were fit to be "the gates of Paradise." Lorenzo brought to this work a great knowledge of composition, a superior acquaintance with the more beautiful forms and movements of the human figure, a refined feeling for expression, and considerable powers of execution. They very far surpass the works of his predecessors in the revival of sculpture, and, in many respects, have not often been excelled. It is not pretended that these reliefs are free from faults. Their chief imperfection arises out of the undefined notions which then existed of the true principles that respectively govern, or should govern, composition in painting and sculpture. It is obviously out of the province of the latter art (which is confined to representing objects by defined forms alone) to attempt perspective appearances and effects which can only be truly and correctly given by aid of colour, or by the skilful distribution of light and shadow. In the work under consideration this principle is invaded. Objects are represented in various planes, and those which should be subordinate are, in consequence of the necessary relief given to them in order to define their forms, forced upon the attention, or cast shadows to the injury of more important features in the design. The number of small parts, and a too great minuteness of detail, are also defects in this remarkable work, and deprive it of that breadth of effect which is so admirable a quality in art. [Ghiberti, Lorenzo, in Biog. Div.]

Donatello was a scholar of Lorenzo de' Bicci, and was born in Florence in the year 1383. The works of Donatello are numerous, and remarkable for their superior qualities. His conceptions were bold, and his execution vigorous, and it is easy to see in his performances the reason for the compliment paid to his statue of St. Mark by one who could so well appreciate these qualities as Michel Angelo: "Marco, perchè non mi parli?" This, and a statue of St. George, also in marble, decorate the exterior of the church of Or San Michele at Florence. The St. George is a fine example of grand and simple expression. The figure, dressed in plate armour, stands firmly on both legs, and he rests his hands on his shield, which is held before him, its pointed base on the ground. There is a calm determination and a quiet dignity in this work. It is probable that the somewhat exaggerated treatment which is observable in this and other productions of Donatello, as well as of Ghiberti, arose from their desire to avoid the dryness and poverty of form in the works of some of their immediate predecessors. [Donatello, in Biog. Div.] Donatello enjoyed a great reputation, and there is scarcely a city of any consequence in the north and middle of Italy that cannot boast some specimen of his talent. He introduced a mode of working reliefs that has not often been practised since his time. The sculptured portion is scarcely raised above the plane of the background. It has the appearance of the design having been drawn on the marble, and then engraved, as it were, under a strong side-light. This kind of work hardly comes legitimately under the name of sculpture, and can only be fitted for certain situations, in which, at a little distance, it has more the effect of a picture than of sculpture.

Brunelleschi, or, as he is called by the Italian historians, Filippo di ser Brunellesco, was contemporary with Donatello. He was an architect as well as a sculptor, and was the originator of the bold idea, which he so successfully carried out, of building the cupola of the Duomo of Florence. [Brunelleschi, in Biog. Div.] Donatello died full of years and honour. He left a brother, Simon, who was invited to Rome by the pope, in 1431. While there he executed one of the bronze gates of St. Peter's. Giovanni di Pisa was another of the numerous scholars of Donatello. There is a large basso-rilievo in terra-cotta by this sculptor over the altar in a chapel of the great church of the Eremitani at Padua, which deserves notice for the simplicity and breadth of the composition, and for the peculiar manner in which it is executed. It represents the Madonna and Child, with three saints on each side, and is remarkable for the flat style of the relief—a mode of working that Donatello frequently adopted, and which, when judiciously managed, has a very broad and fine effect.

Italy was at this time filled with artists, many of them of distinguished merit, who found ample employment in what may be called church sculpture, and occasionally in executing statues of illustrious persons. Florence perhaps boasted the highest names in the several arts, but Bologna, Padua, Milan, Naples, Siena, Venice, Modena, and even the smaller cities of Italy, all had their schools of artists. The Majani and the two Pollajoli, Andrea Verrochio, Andrea Ferrucci, and

Mino da Fiesole, are among those whose works claim attention among the best productions of the 15th century.

Andrea Verrochio is chiefly celebrated as having been the master of Lionardo da Vinci, and of Pietro Perugino, the master of Raffaelle. It is said that Verrochio was at first a painter, but having desired Lionardo da Vinci, then a mere lad, to paint an angel in an altar-piece on which he was engaged, Verrochio found the performance of the scholar so superior to his own portion of the work, that in a fit of jealousy he resolved to paint no more, and he soon after devoted himself to the sister art. A bronze equestrian statue of Colleoni, by Andrea Verrochio, may be seen at Venice in the Piazza di S. S. Giovanni Paolo; it is interesting as a specimen of art of the time, but it is heavy in form, and the action of the horse is not true to nature. Verrochio provided the design and model for this group. It was cast in bronze by Alessandro Leopardo. Several of the works of Andrea are preserved at Florence.

It is a reproach to the artists of the 14th and 15th centuries, that, not satisfied with carrying out their own original ideas, and endeavouring to advance the practice of art within the limits of consistent design, they suddenly had recourse to the incongruous mixture of ancient mythology with the existing religion, an unfortunate innovation which tended to check the steady progress of sculpture by engrafting a totally foreign class of design or ideas upon their own original sentiment; they only misused or abused the one, and at the same time materially injured the effect of the other.

Michel Angelo Buonarotti was born in 1474. At an early age he became the scholar of Domenico Ghirlandajo, the most celebrated painter of his time, and afterwards studied under Bertoldo, the director of the academy established by Lorenzo de' Medici at Florence. The genius of M. Angelo was remarked by Lorenzo, who received him into his house, giving him apartments in the palace, and otherwise honouring him with marks of peculiar favour. As he increased in years, his wonderful powers as an artist were developed; and his powerful and vigorous genius placed him at once in the distinguished station which he still occupies. Till the time of Michel Angelo, the works of art since the revival were all more or less meagre and dry in style, although considerable feeling and talent were occasionally displayed in their conception (or invention) and composition. Extraordinary efforts were sometimes made, as by Ghiberti and Donatello, to infuse into them a better and more elegant quality of form; but it was left to Michel Angelo to effect that total revolution in style which has stamped not only his own productions, but the art of his age, with a character peculiarly its own. The most striking quality in the works of Michel Angelo is an undefinable vastness and grandeur of effect that takes entire possession of the mind. This power is strongly felt in the presence of his colossal statue of Moses, in the monument of Pope Julius II., and of his statues of Lorenzo de' Medici (not "il Magnifico") and Giuliano de' Medici, in their monuments in the family chapel at Florence. The Moses is a grand effort of genius. It is as original in conception as it is masterly in execution. The characteristic feature of this statue is its vast energy; but it is sufficiently tempered to preserve the repose which is essential to true dignity. This work requires to be studied with attention: its merits will then be found to compensate for those minor faults which at first sight offend the fastidious spectator, and which, it must be admitted, the manner of Michel Angelo threw more or less into most of the productions of his chisel and pencil. As a whole, it illustrates the forcible expression applied to the general character of this artist's works, "*Di Michel Agnol' la terribile via.*" The statue of Lorenzo is also seated. He is represented absorbed in thought. He rests his face upon his hand, which partially covers the chin and mouth. The general action is one of perfect repose, and the expression that of deep meditation. It is impossible to look at this figure without being forcibly struck with the *mind* that pervades it. For deep and intense feeling it is one of the finest works in existence. It has been well observed of this statue, that it has no resemblance to the antique, but it rivals the best excellences of the ancients in expression combined with repose and dignity.

In the lower part of the two monuments of Giuliano and Lorenzo, in the chapel of the Medici, are allegorical figures of Day and Night, and the Dawn, or Morning and Evening. They bear the impress of the master-mind and hand; but the violence of action and forced expression of these statues are not in character, in the first place, with the repose which is appropriate to monumental sculpture, and they do not harmonise with the figures above them. The intimate knowledge of anatomy possessed by Michel Angelo, and the evident mastery he had over all difficulties of execution, appear sometimes to have tempted him, as in these statues, to indulge in their display at the expense of propriety of design.

In the Minerva Church at Rome is a much admired statue of Christ by M. Angelo. It has less of violence of action than usually characterises his works; but though it has qualities of a high order, and displays great knowledge of form and skill in execution, it is by no means one of his most successful efforts. The figure wants that calm dignity and refinement which should pervade the representation of the divine nature under a human form. Another work of Michel Angelo, which is often referred to as a specimen of this master, is the statue of David, in the Piazza del Gran Duca at Florence. The powerful hand of the great sculptor is visible in it, and the grand air that is given to the figure by the turn and expression of the head and throat justly claim our admiration; but it is not one of Michel Angelo's finest works. It was executed under very unfavourable circumstances, Buonarotti having been called upon to finish it when the block had already been worked upon by an inferior artist, and considered to be spoiled. In the gallery of Florence is a half-drunken Bacchus, also the work of this sculptor. An ancient subject, it still has the merit of being filled with Michel Angelo's own feeling for character and expression, but it falls short of the manner in which the Greeks would have treated it. It wants purity of taste, and the beautiful form, free from affectation or display, which the ancients knew so well how to apply in all their conceptions. Michel Angelo in this work attempted to represent what he could not feel as a Greek sculptor would, and to this only is to be attributed its inferiority. Among the best known groups by Michel Angelo are the Madonna and Child, in the chapel of the Medici at Florence—unfinished; a Pietà, in a small chapel at St. Peter's at Rome; and a group of Nicodemus supporting the dead body of Christ, with the Madonna and Mary Magdalen. These, as compositions, are of the highest merit. They also abound in pathos, and are in many respects finely executed. The Dead Christ, in the Pietà, is particularly worthy of attention. The tranquillity and perfect repose of death are most successfully shown throughout this figure, and with some slight exception (in the face and in the articulations of the joints, in which the usual exaggeration of Michel Angelo is perceptible), it must be considered one of his finest productions. His works in relief are not very numerous. We possess in this country one in marble, of very great merit, consisting of three figures, representing the Virgin, the infant Christ, and St. John. It is unfinished, but the master is declared in the composition of the group, in the grand style of the forms, and in the bold and vigorous character of the execution. It is in the Royal Academy of Arts, having been bequeathed to that institution by the late Sir George Beaumont, who purchased it in Italy. There is another work very similar to this, and like this also unfinished, in the Gallery of Sculpture at Florence. In the Vatican is another of a different class. It is an allegorical subject, and is a monument of the perfect knowledge of the human figure possessed by Michel Angelo; but it is more remarkable for this than for other qualities requisite in sculpture, namely, simplicity and unity of design. The composition is both crowded and complicated. In taking this rapid survey of some of the principal works of this master, the object has been to bring before the reader the most celebrated of his productions, in order that the accompanying observations might be immediately applied to well-known examples, and the characteristics of his school be more easily understood. Notwithstanding our admiration of the originality of invention, the vigour and mental energy, the knowledge of anatomy, and mastery of execution that appear in his productions in this art, it is generally admitted that the sculpture of Michel Angelo does not give that high satisfaction which is felt in the contemplation of the best works of ancient and some even of modern times. [BUONAROTTI, MICHEL ANGELO, in BIOG. DIV.]

Michel Angelo has had many imitators who have had neither genius nor originality to compensate for the imperfections which are overlooked or forgotten in the mighty inventions of the master-mind, and who for the most part have only been able to copy and increase the faults of his style. Michel Angelo died in 1564, and was buried in the church of Santa Croce in Florence, and a monument is over his grave in which there is a basso-rilievo, by himself, of a Madonna and Child. The design of this "deposito" consists of a bust of Michel Angelo over a sarcophagus, in front, and on each of which are statues supposed to represent Painting, Sculpture, and Architecture. The bust and the statue of Sculpture are the work of Lorenzo, one of his scholars; those of Painting and Architecture are by Valerio Cioli and Giovanni dell' Opera.

There is a group, in marble, in the Chigi Chapel, in the church of Santa Maria del Popolo at Rome, representing Jonas with the sea-monster, which is remarkable for the grand style of its composition, as well as for the breadth and beauty of its forms. It is attributed to a sculptor who lived in the 16th century, called Lorenzetto, but there is a tradition that the design was furnished by Raffaelle, and that he even made the model from which the sculptor executed the marble figure. Michel Angelo had a very high opinion of the works of Beggarelli, a sculptor of Modena, and is said to have exclaimed, on being shown some of his models, "If this clay could but become marble, woe (*guai*) to the antique."

Jacopo Tatti, better known as Sansovino, is more deserving of celebrity as an architect than as a sculptor. [SANSOVINO, in BIOG. DIV.] His chief productions, in both arts, are at Venice. Some statues on the Scala dei Giganti (the Staircase of the Giants), at the Palace of the Doge at Venice, and some bassi-rilievi in other places, especially a bronze gate at St. Mark's, are examples of his ignorance of or indifference to the true principles of design in sculpture, though it would be unjust to refuse them the merit of much elaborate execution. Many of his scholars became distinguished artists. Among them may be mentioned Nicolo Tribolo, Danese Cattaneo, some of whose works are in the church of S. Antony in Padua, Bartolomeo Ammanati, Alessandro Vittoria, a sculptor of great merit, and probably Tommaso Lombardo. About this time a profusion of ornament began to be associated with works in sculpture, and led artists to neglect the simpler qualities of design for high finish and minutiæ of mouldings, flowers, scrolls, and other objects of minor importance. Among the ornamented works of the *cinque cento* which are most worthy of notice, are the splendid altar candelabra in some of the Italian churches. There are some particularly fine specimens of this kind of work at Venice. Baccio Bandinelli, born in 1487, is among the distinguished contemporaries of Michel Angelo, Sansovino, and the great sculptors of that time. [BANDINELLI, in BIOG. DIV.] Although some exaggeration in design and defects in execution may be visible in his works, they possess qualities which claim for their author a distinguished place among modern sculptors. There are some bassi-rilievi in marble, by Bandinelli, round the screen of the high altar in the Duomo of Florence, which are admirable for their breadth and the fine treatment and disposition of their draperies. The fault of his composition generally, whether of one or several figures, is in its too picturesque arrangement, and in his placing his figures in somewhat forced and affected attitudes. The restoration of the right arm of the celebrated group of the Laocoon was entrusted to Bandinelli. Some critics believe this arm should be turned back, and that the hand or some part of the serpent should touch the head of the figure. [LAOCOON.] In Bandinelli's restoration the arm is extended.

There is a work of considerable merit, and also of some interest from the circumstances under which it was executed, in the church of S. Petronio at Bologna. It represents the story of Joseph and the wife of Potiphar, and is the production of Propertia de' Rossi, a lady of great personal beauty, and highly accomplished in various branches of the fine arts. It is said she became enamoured of a young artist who did not return her love, and the disappointment threw her into a languishing disorder which terminated in her death. Her last work was the basso-rilievo above mentioned. In it she represented herself as the wife of Potiphar, and the object of her affection as Joseph escaping from her. She died in the flower of her age, in the year 1530.

Benvenuto Cellini, born in Florence, in 1500, was one of the most distinguished sculptors, founders, and chasers in Italy. All his larger works are in bronze, and are preserved in his native city; but numerous specimens of his skill in smaller productions, as medals of gold and silver, bucklers, dagger hilts, and tasteful ornaments, are in foreign collections and afford ample evidence of the superior talents of their author. The particulars of his life and the history of many of his works are graphically told by himself, in one of the most entertaining autobiographies extant. [CELLINI, BENVENUTO, in BIOG. DIV.]

The list of sculptors of this school, or rather of this division of time (for each effected changes that tended to interrupt the existence or continuance of schools), must close with Guglielmo della Porta, the most skilful of all the artists of Lombardy. He was the scholar of Pierino del Vaga. He was also a favourite of Michel Angelo, from whom he received a very high compliment. Guglielmo had been employed to restore the legs of the famous Hercules (now called the Farnese) of Glycon, which he did so admirably, that when, after a time, the original legs were found, Michel Angelo was unwilling to remove Della Porta's for those which had so unexpectedly been recovered. Della Porta executed few works. The most remarkable, as an example of the influence of the style both of Michel Angelo and of Raffaelle, is the monument of Paul III., in St. Peter's at Rome. Two recumbent statues in this work, one a female of advanced years, representing Prudence, and the other, a young and beautiful woman, as Justice, are particularly fine. The latter figure is deficient in the expression and character proper to the subject, but it is a remarkable performance for the roundness and richness of its execution, and for the knowledge of form displayed in it. This statue was originally naked; since Della Porta's time it has been partially covered with bronze drapery. This artist effected some changes in the process of casting in bronze. [BRONZE.]

At the end of the 16th and the beginning of the 17th centuries, the sculptors aimed chiefly at fine and curious execution. The works of that time exhibit very high merit in many respects, but they are deficient in repose and simplicity. Instead of grace, we find affectation, and mechanical skill was held in higher estimation than what may not improperly be called the moral qualities of art. The works of Giovanni di Bologna, a native of Flanders, but established in Italy, offer ample illustration of this meretricious and destructive taste in sculpture. They are full of imagination, and are executed with a boldness and ability that both surprise us and call forth our admiration, but there is at the same time an exaggeration in the attitudes and an endeavour after picturesque effect that disappoint us. One of the most remarkable performances of this artist is his well-known group, in marble, of the Rape of the Sabines. As a specimen of invention it is wonderful for its expression and its energy of action; and it is impossible not to admire the courage of the sculptor who ventured to execute so daring a work in such a material; but it is open to criticism for the extravagant corkscrew contortions of the composition. His famous bronze statue of Mercury is conceived in the true spirit of poetry, and is deservedly admired as one of the most elegant productions of modern art. The form is light, and the action graceful. He had many imitators, who, like copiers in general, chiefly exaggerated his faults. There are few works of Stefano Maderno, but there is a simplicity of composition and a beauty in the sentiment of his statue of St. Cecilia, that justly claim for him a place among the most worthy of the sculptors of this age. This statue was executed when he was very young. The supposed body of St. Cecilia was found in Rome, in 1599, during the pontificate of Clement VIII., and Stefano Maderno was employed to make a careful copy of it before it was removed to where it now lies, in the church of the convent dedicated to this saint in Rome. This may account in a great measure for the superiority of this work over others by the same artist. Limited by the circumstances, and by the pontiff's command to take nature as his model, he had no opportunity to introduce any of the prevailing bad taste. The result is a work of great beauty, one of the best of that age, and in certain qualities not surpassed by later artists.

Bernini was born at Naples, in the year 1598. [BERNINI, in BIOG. DIV.] He possessed genius, imagination, ambition to excel, unceasing industry, and great powers of execution; and still, with all these means and dispositions, he was, beyond all others, instrumental in precipitating the decline of sculpture; and the tendency, already exhibited, to prefer minute execution to the higher qualities of design, was confirmed by the popularity it acquired in the hands of this artist.

It would be difficult to conceive two styles more opposed to each other than that adopted by the sculptors of this age and that of the great artists of antiquity. In one the pervading principle was simplicity and expression, united with beautiful and appropriate form. In the other, simplicity was of all things most studiously avoided; and complicated arrangement in composition, forced action in the figures, flying draperies, elaborate carving, and undercutting (in works in marble), and other means of little more than mere mechanical display, were resorted to, in order to create surprise or to please the eye. Under Bernini all the distinctive bounds of the classes of art were trampled down. Sculptors endeavoured to imitate the effects of the pencil, and architects to introduce into their compositions the curved line of beauty.

The faults and merits of Bernini as a sculptor will be best shown by a reference to and criticism of a few of his best known works. His group of Apollo and Daphne, in the Villa Borghese, is a production of great merit for its invention and power of telling its story. The god has just reached the object of his pursuit, and, at the moment when he seizes her, Daphne's prayer is heard, and the beautiful form is being metamorphosed into a tree. Instead of generalising this part of the history, Bernini appears to have delighted in the opportunity of showing his skill in execution. The hair and drapery of Apollo are floating in the air, while the change that is to preserve Daphne from violence is shown in detail, in her tresses, the toes and fingers becoming elongated into roots and branches, the latter terminating in carefully-worked laurel-leaves. St. Peter's at Rome contains various works of this artist. The most remarkable of these are the splendid monuments of Urban VIII. and Alexander VII., which may be said to exhibit all his excellences and all his defects. The former stands opposite a celebrated work of Guglielmo della Porta before mentioned (the monument of Pope Paul III.), and is a melancholy proof of the consequences of losing sight of purer principles. Della Porta's was not a school of perfection; but the contrast between the grandeur of manner of his time and the handicraft display of Bernini's period is distressing. The composition of the second work alluded to, the monument of Alexander VII., is as strange as the execution is wonderful. The sitting figure of the pope occupies the centre of a large and deep niche. The whole of the lower part or ground is filled up with curtain and cloud, in the corners of which are plunged four allegorical groups or figures. Of those at the back of the recess but little can be seen except the heads and shoulders. In the front corners are Truth and Charity, the latter a gigantic female, with fleshy infants pressed against her breast, to whose weight the marble appears to yield with all the elasticity of a soft pulpy substance. This work is a triumph of execution, but debased by the worst taste. A group of the Extacy of St. Teresa in the church Della Vittoria at Rome is another instance of the want of simplicity. In this it is difficult, amidst the flutter of the drapery and the ample convolution of clouds, to discover either the figure of the saint or the subject of the composition. The Four Doctors of the Church supporting the Chair of St. Peter, in the church of that apostle at Rome, is a grand idea; but its effect in execution is injured by the want of simple unaffected expression and attitudes. These statues are colossal. They are cast in bronze, and some parts of the figures and draperies are richly gilt. This composition, taking it altogether, has a magnificent effect. Fontana calculated, from the archives kept in Rome, that this work must have cost a hundred and seven thousand crowns. Bernini lived during nine pontificates; from that of Clement VIII. to Innocent XI. No artist ever had greater patronage, and few greater talents, which, unfortunately for sculpture, were ill-directed, or at least ill-disciplined; the variety of his pursuits and his inordinate love of picturesque effect ruined the progress of the art, induced a false taste in patrons and artists, and, from the injury effected by his bad example, it may safely be said that it would have been better for sculpture if Bernini had never lived.

Alessandro Algardi, a native of Bologna, was contemporary with Bernini, and executed many works of merit. Like other sculptors of the time, he was tempted away from the more valuable qualities that should characterise sculpture, by the endeavour to gain distinction by the display of execution and the picturesque effect of his compositions. The great work of Algardi is his alto-rilievo, preserved in St. Peter's, of the discomfiture of Attila by the miraculous appearance of St. Peter and St. Paul. This work is in marble, in five pieces, and measures about thirty feet in height by nearly eighteen in width. Algardi studied the paintings of his contemporaries for the manner of treating his subject; and the consequence is such as might be expected in an art in which it is totally impossible to produce those effects of distance, clouds, and perspective which only can be given by colour. There are merits in parts of this great composition, which increase the regret that is felt at the faults that are so apparent in other portions of it. In the unpleasing task of following the traces of this decay, it is refreshing occasionally to find examples of a purer taste. Francesco di Quesnoy, better known from his title of Il Fiammingo, was a native of Brussels. His early works are said to partake very much of the character of those of Bernini and Algardi; but it is recorded that he was led to copy and study very young children (*putti*), from admiring the beauty of those introduced into his pictures by Titian, and he ultimately became the first sculptor in this class of representation. There are few, whether they have travelled or not, who have not had an opportunity of admiring some specimens of this artist's skill in the round, healthy, playful character of his infants. No artist, except perhaps Raffaelle, ever succeeded so entirely in portraying the peculiar charm of beautiful childhood. He preserved just the right medium between tameness and exaggeration. In the church of La Madonna di Loreto at Rome there is a work by Fiammingo, which represents St. Susanna, and it may fairly be considered one of the most successful efforts in sculpture of the age. The expression of the head is especially worthy of attention. It has simplicity and intenseness combined with considerable beauty of form. Francesco Mocchi obtained a high reputation in his time. The work by which his merits may best be judged of is in the Duomo of Orvieto. It represents the Annunciation, in two distinct figures. The angel is supposed to be descending, and is supported on a cloud; while the Virgin, in an attitude of shrinking modest fear, is bowing her head as she receives his announcement. Its faults are the faults of the age,—a want of simplicity and too much of the picturesque in effect. As examples of elaborate execution, further illustrating the decay of pure taste and the fall of sculpture, the works of San Martino and Corradino may be noticed. Some statues by these artists are preserved at Naples, in the church of S. Severo. One represents the dead body of our Saviour, covered with drapery, under which may be traced all the forms of the figure: a piece of ingenuity of no very difficult attainment, but which always surprises and delights those who are ignorant of the mechanical processes of sculpture, and who think that whatever has the *appearance* of being difficult in art must be so, and measure out their admiration according to their estimate of the ingenuity with which it is overcome. The other is a figure of Modesty, veiled. There is also a third statue, of Deceit, within a net—a very curious piece of execution. These works attest the patience of their respective authors, and are monuments of their bad taste.

The works of the contemporary and immediately succeeding sculptors do no more than prove the rapid consummation of the fall of sculpture. Occasionally an artist of better taste or higher feeling appeared; but he was not seconded or supported by any refined feeling in patrons, nor inciting sympathy in the public, and the enumeration of works by the Rusconi, Bonazzi, Tagliapietra, Torretti, Morlaiter, Foggini, and others, would assist but little in conveying any distinct impression of the slight shades of difference in the generally fallen and decayed practice of the art.

In the general survey of the rise, progress, and decline of sculpture in modern Italy, may be seen, very nearly, the history and condition of the art in other European countries. The artists of Italy spread themselves over the Continent, and wherever works of design were required they probably were called upon to execute them. The influence of the taste of the schools of Lionardo da Vinci, Primaticcio, Benvenuto Cellini, Rustici, and others, will be visible in the works of their different times, in France and other countries; and even when it can be ascertained that sculpture was produced by native artists, it generally will be found that their knowledge of art was due to Italian models or Italian masters.

The French historians attribute to native artists the tomb of Philip le Hardi, which was executed in 1404, as well as that of Francis II. The first sculptor who really was distinguished in that country was Goujon. He executed various important works in the 16th century. Among the most distinguished sculptors of succeeding times may be honourably mentioned Pilon, Anguier, Puget, Girardon, Le Poutre, Le Moine, and Coustou; but sculpture soon became decorative in France, and flutter in composition and design, and minuteness in execution, characterised their art almost from the 16th century to a very recent period. The extreme of the worst style of French sculpture is seen in the monument of Marshal Saxe by Pigal, which was erected about the year 1775.

The earliest sculptors of Spain who are mentioned by their historians of art are Aparicio and Rodolfo, who lived about the year 1033. The next is Jayme or Jacques Castyls of Barcelona, who is said to have executed various statues in the façade of a church at Taragona in the year 1376. The name of Anrique occurs in 1380, and of F. Gonzalez in 1399. It seems, however, that no great progress was made in the arts in this country till the 16th century, when Spanish artists went to Italy to study, or Italian artists established themselves in Spain.

The history of sculpture in Germany would lead us into a wide field of inquiry. It is not necessary towards illustrating the general history of the progress of the art, which may be traced with sufficient accuracy through the different Italian schools; and the examination of the causes of its rise and the changes of style it has undergone amongst the Germans would carry us into speculation, or at best into its merely national or local history, rather than assist us in giving a general and comprehensive view of the art. Läffler, or Löffler, is said to have executed the bronze statues which stand round the tomb of the Emperor Maximilian at Inspruck: he died in 1565. Others attribute them to two brothers of the name of Godi, who lived at the beginning of that century. The latter name suggests the probability that artists from Italy were then established in Germany, or were called upon to execute works of this description.

The political disorders in which Italy was involved in the earlier part of the 18th century, may account in some measure for the inactivity in which the arts remained for some years. The wars of the Succession in the kingdom of Naples, the change of dynasty in Florence in the year 1737, and the unsettled state of other parts of the country, diverted men's minds from such pursuits. Cicognara attributes much also to the debased or degraded state of feeling among his countrymen. But his condemnation is more general and severe than appears to be warranted by facts, and it certainly seems unjust to attribute to the moral degradation of Italians of the 18th century the decline of art which had commenced so long before. It is admitted that, prior to this time, taste in art had greatly deteriorated. The effect of the state of feeling described as existing in this later time was to leave sculpture in its fallen state, when a little energy might possibly have restored it. From 1748 to 1796 Italy enjoyed an uninterrupted course of peace; and it is true that during that period there scarcely was a work in sculpture of any magnitude or comparative excellence produced.

The first sovereign who contributed to revive the arts from this state of torpor was Charles III. of Naples. He encouraged architecture on a grand and extensive scale. At Rome, Cardinal Albani formed a collection of the finest remains of ancient sculpture that could be procured; and by attaching to him all the most distinguished litterati and the best artists of his day, made his palace the resort of all who felt an interest in the pursuits to which he himself was so devoted. Under the auspices of this "Hadrian of his age," as Cardinal Albani has been justly called, Winckelman produced the first work in which the history of the arts of design had been treated in a learned, philosophical, and scholar-like manner; and it has been the model and groundwork of all succeeding and improved works upon the same subject. The popes Clement XII. and Benedict XIV., as well as Clement XIII. and Clement XIV., contributed also to create a feeling for the sculpture of the ancients by accumulating monuments of various kinds in the pontifical palace. To Clement XIV. we are indebted for the foundation of the Museo Clementino in the Vatican, which received such noble additions by the liberality of his successor, Pius VI., that the name of the latter pontiff was associated with that of its founder in giving a title to the collection, and a considerable portion of the gallery of ancient sculpture is still known as the Museo Pio-Clementino. Till Pius VI. issued an order to prevent the removal of works of art, the remains of antiquity discovered in Rome and its neighbourhood could be sold and taken out of the country. The pope, desiring to increase his collection, and preserve to Rome whatever could be recovered by excavation, prohibited anything being removed out of his dominions without a special permission. This order procured for his agents the first choice of whatever statues or other monuments of sculpture were found; and the extensive purchases effected by this means soon filled the Vatican with works of ancient sculpture, which, with the additions made by succeeding popes, have made it the most celebrated, as it is the most valuable, collection of its kind in the world. The discovery of the long buried remains of art in Herculaneum and Pompeii led to the formation of a museum of the same kind at Portici; and, in bronzes especially, the Neapolitan collection is without a rival. Among the sovereigns of Italy who contributed to the revival of design, Leopold, grand-duke of Tuscany, must likewise be included. The sculptors of this period were Cavaceppi, Penna, and a few others, in whose hands sculpture made some progress towards a more healthy state. The immediate influence of the Bernini school had ceased to be felt, and the opportunity was given, which these artists in some degree availed themselves of, to introduce art upon purer principles. It must be admitted that what they produced was eminently deficient in original feeling, and their best works were little more than somewhat tame copies or adaptations of ancient subjects and models; but at least the practice of the art was continued, and when men of greater power and more vigorous minds appeared, they had not to begin afresh from the infancy of sculpture, nor from the miserably low point to which the Bernini manner had reduced it. Before touching upon the most celebrated sculptors who reformed and restored the taste for art in our age, we shall take a rapid survey of the history of sculpture in England.

The Britons had not the advantage of very skilful instructors in the Roman soldiers by whom the country was so long held in subjection;

but during this foreign dominion the native inhabitants had learned to adopt many of the arts. The making of arms and coining money had also taught them some important processes in the more refined arts, and the knowledge thus acquired was not allowed to fall into entire disuse; and it appears that, after the departure of the Romans, the Britons continued to practise some branches of sculpture. Speed (quoted by Flaxman, 'Lect.' I.) says that "King Cadwallo, being buried in St. Martin's Church, near Ludgate, his image, great and terrible, triumphantly riding on horseback, artificially cast in brass, was placed on the western gate of the city," &c. The workmanship of this "great and terrible" statue was doubtless very rude and barbarous, but it is interesting to find the tradition of a work of art cast in brass in this country at so early a date. The death of Cadwallo is placed at A.D. 677.

The edifices erected in England after the final settlement of the Saxons in this country, and down to the reign of Henry I., seem to have been nearly in the same style, exhibiting plain fortress-like construction, and repetitions of heavy columns and arches. Sculpture was so little employed, that it is believed there is no sepulchral statue in England of earlier date than towards the end of the 11th century, though the French had begun to decorate their coffin-lids with figures, &c., as early as the 9th. We may conclude, therefore, that this practice was first introduced into the country at the Norman invasion.

All the oldest monuments in which figures are thus represented are of ecclesiastics. Two specimens of these sculptured effigies, carved in very low relief on coffin-shaped slabs, may be seen in the cloisters of Westminster Abbey. They are supposed to represent two abbots, Vitalis, who died in 1087, and Crispinus, who died in 1117. Similar monuments are preserved in Worcester cathedral, of St. Oswald and Bishop Wulstan. These sculptures, of extremely rude design and workmanship, have been much injured by time and violence, but they are curious as the earliest examples of the kind in this country. It has been thought probable that one reason for not decorating with figures, or any distinguishing device, the stone coffins in which more illustrious persons were enclosed, was to preserve them from the chance of violence which might have been offered to them, in order to gain possession of the ornaments that usually were deposited with individuals of exalted rank. Several monuments of bishops and abbots which have been opened have shown the deceased fully habited in his episcopal robes, with his ring on his hand, and an enriched crozier either lying by his side or across the body. The more sacred character of the occupant of the tomb, and of the objects buried with him, might prevent any indignity being offered to them; but kings and princes would not be considered in the same view, and, as they would no doubt be even more richly dressed than ecclesiastics, however high their rank, their tombs would offer greater temptation to sacrilegious avarice. The circumstance of the tomb of William Rufus in Winchester cathedral being entirely devoid of ornament may be thus accounted for. That of Gundred, daughter of William the Conqueror, at St. John's church, Southover, is inscribed, and embellished with foliage, heads, and other decorations, but there is no figure of the deceased on it.

When the Crusaders returned from the Holy Land, they endeavoured to introduce into England a taste for the magnificence they had witnessed in foreign countries, and imitations were attempted of the rich foliage and other decorations employed in their architecture. In the west door of Rochester cathedral are some figures so applied.

We believe the earliest specimen in England of figures in armour is of the time of Richard I. Those in the Temple church, of Magnaville or Mandeville, earl of Essex, and of two other knights similarly habited, are probably of this date.

The first example that occurs in England of a monumental figure in royal costume is that of king John, on his tomb in Worcester cathedral. An interesting proof that the figures carved on the lids of tombs were tolerably accurate representations of the persons whose remains they contained, was afforded by the opening the coffin of king John in the year 1797. The body, &c., was in a state of sufficient preservation to show that it had been dressed in precisely the same costume as that represented in the sculptured effigy.

Wells cathedral was built by Bishop Joceline, who died in 1242. The west front of this church is richly studded with sculpture, consisting of representations, in relief, of Scripture subjects, and of statues, many of them of colossal dimensions, of kings, queens, saints, bishops, and other patrons or dignitaries of the church. This work must have been in progress at the time that Niccolo Pisano, the restorer of sculpture in Italy, was exercising his art in his own country. Flaxman ('Lectures on Sculpture') thinks that the greater part of the sculpture was by English artists. Some of the statues exhibit much grace and simplicity, and, allowing for the very rude state of art at the time they were produced, they deserve the attention of the curious. The sculpture of the succeeding reign was probably by Italian artists, scholars, or imitators of Niccolo Pisano, who travelled about in search of employment in those countries where ecclesiastical buildings were being erected. The richly decorated crosses that were raised to distinguish the spots wherein the body of Queen Eleanor rested, were probably by these artists, as well as the statues of Edward I. and Eleanor in Westminster Abbey. The flat brasses with figures sculptured, or rather engraved on them, and let into stone slabs, are mostly of the 14th century, few being met with earlier than the reign of Edward II.

Under Edward III. it appears that our own countrymen were capable of exercising some branches of the arts of design. Many specimens of that date remain to prove both the extent to which sculpture was employed, and the merits of the artists by whom the several works were executed. Some interesting examples of art of the 14th century may be seen in three recumbent statues in memory of the sons of Edward III.: one is of the Black Prince, in Canterbury Cathedral; another of Prince William of Windsor, in Westminster Abbey; and the third of Prince William of Hatfield, in York Minster. These works were executed between the years 1344 and 1378. There are also three remarkable windows of this date at Dorchester Church near Oxford: one of them is adorned with between twenty and thirty small statues relating to the genealogy of our Saviour; the others contain reliefs representing Scripture subjects. Various other equally interesting works, exhibiting the progress of the art, belong to this date; and the names of several English artists employed by Edward III. at Westminster are recorded. ('History of Westminster Palace,' by Smith; Flaxman, &c.) The figure, in plate armour, of Beauchamp, Earl of Warwick, on his tomb in the Warwick Chapel, with the numerous smaller statues let into niches around it, is the work of William Austin, an English sculptor and founder. It was executed in 1439.

The chapel of Henry VII. in Westminster Abbey is one of the most beautiful specimens of rich architectural decoration that exists in this or perhaps any country. The statues within and without it are said to have amounted originally to 3000, but the number is probably exaggerated. An Italian artist, Torreggiano, assisted in the construction of this magnificent tomb; but there is strong reason to believe he was employed on the tomb only, and that the greater portion of the sculptures in other parts of the chapel were executed before he arrived in the country, and it is presumed they were the productions of native artists. Some of these statues show a beautiful feeling for art, and are well worthy of attention for the simplicity and grace of their action, and for the tasteful arrangement and careful execution of the draperies.

From the reign of Henry VIII. to Charles I. sculpture fell into neglect. Indeed it frequently happened that, during the religious animosities and the party violence that prevailed, works of art, and more especially works of sculpture, were purposely destroyed. Charles I. showed a strong disposition to encourage the arts. The celebrated Cartoons of Raffaelle were purchased by order of the king, and, with other fine works, were brought into this country. In this reign we meet with the names of English sculptors. Christmas executed a monument to Sir William Pitt and his lady, at Strathfieldsay in Hampshire; and Stone is the author of a monument in Westminster Abbey, in memory of Sir George Holles, which is not without merit. Generally speaking, however, the style and composition of these and other works of the time are utterly worthless, but there is some boldness occasionally in the conception, which may claim for them a passing notice. The sculpture on the pedestal of the Monument of London, representing Charles II., attended by allegorical groups, raising the City of London (under the form of a prostrate female figure), is a striking example of the pseudo-classical and false taste, in art, of the 17th century. After this time, the principal works in England were by foreigners; and the names that most frequently occur are Cibber, Steevens, De Vere, Bertocini, Scheemacker, and Roubiliac, as the authors of monuments and whatever other productions were required in sculpture. This variety of artists, as Flaxman observes, from different countries, — French, Flemings, and Italians, — sometimes brought the taste of Jean Goujon or Puget, sometimes a debased imitation of Giovanni di Bologna and the Florentine school, and sometimes the taste of Bernini, but never a pure and sound principle. In 1766 an English sculptor, Nathaniel Read, executed a monument, which may be seen in Westminster Abbey, in memory of Admiral Tyrrell. It would not be easy to convey by description any just idea of the strange conceits and incongruous imagery that abound in this work; and without the aid of the inscription it would be impossible to comprehend the purpose and subject of the artist's ingenious, and, it may truly be said, costly labours. Admiral Tyrrell died at sea, and his body was committed to the deep. In the lower part of the composition are three allegorical figures, life-size; one of them represents Ireland, as the admiral, we are told, was descended from an ancient family of that country, and above is the apotheosis of the deceased. The 'Historical Description of Westminster Abbey,' after giving the explanatory inscription, notices the work in the following words: "On a piece of rock—'The sea shall give up her dead, and every one shall be rewarded according to his works.' The figures of History, Navigation, and Hibernia are well cut; they are represented among the rocks, with the sea above their heads, the admiral himself ascending amidst heavy clouds." This fully describes the style of the art during the greater part of the 18th century. Allegorical pictures were executed in stone and marble, and it was absolutely necessary to have explanations attached to the work in order to enable the spectator to comprehend the meaning of the sculpture. The monuments contain every variety of a most confined idea; and Time, Fame, and Death, represented in the most absurd, and often most objectionable forms, are made the accompanying illustration to almost every work on which the sculptor was employed.

The works of Roubiliac, with all their defects, have merits which redeem them from this general and deserved condemnation [ROUBILIAC, in BIOG. DIV.]; but, with the qualified exception in his favour, the productions of the artists who practised with him, and after his death, can only be classed in the lowest grade of art; it is impossible to imagine anything more false and poor than the style that prevailed.

Early in the present century, the first step was taken towards forming in England a national collection of ancient works of art. The Townley Marbles were purchased by a grant of parliament, and placed in the British Museum in the year 1808. Since this period the collection has been enriched by the addition of the Athenian (or Elgin) Marbles, the Phigalian Marbles, the Lycian and Xanthian Marbles, the rilievi discovered by Layard and his successors, at Nineveh, and the sculpture still more recently found on the site of the mausoleum at Halicarnassus, together with various fine bronzes, and other valuable specimens of ancient sculpture.

The honour of giving a new direction to taste, or rather, of leading it back to a recognition of true principles, is eminently due to Flaxman and Canova. "To Canova Italy owes her emancipation from those false perceptions which had, from the influence of the Bernini school, so long diverted the current of pure taste. . . . . To Flaxman the art owes equal obligation. Banks had corrected the grosser impurities, and had stemmed the torrent of bad taste." "No modern sculptor has entered so deeply into the recesses of ancient art as Flaxman; his style was founded upon their principles, combined with the simplicity of the Pisani and others of the 14th century." The above short extracts from the address of Sir R. Westmacott, who succeeded Flaxman as professor of sculpture in the Royal Academy, place the merits of these two distinguished artists—the restorers of sculpture—in their true light. In the Theseus of Canova, one of his best and earliest works, we recognise the long-lost purity of form and a decided devotion to the simplicity of the antique. In the designs of Flaxman simplicity, grace, and expression resume their influence, in place of the affectation and display of fanciful ingenuity that had so long prevailed. The later works of Canova show a tendency in that great artist to a more minute execution and attention to small parts than is quite consistent with the best taste in sculpture; and it may be objected to Flaxman, that, in his admiration of the beautiful and impressive in design, he too often neglected the means of making his works effective in execution; but it is not expedient to enter here into a critical examination of their respective merits and defects. Their works, the best evidence of the superiority of these distinguished sculptors, are before the world, and a comparison of their productions with those of the entire series of artists from the time of Michel Angelo (and the best of his immediate followers) down to our own age, will at once exhibit their merit in its true point of view—in the influence they have had in restoring a degraded and fallen art to its proper position.

Mechanical Process of Sculpture.—The technical or mechanical processes of sculpture are for the most part extremely simple. The sculptor, having conceived or invented his subject, usually begins by making a slight sketch of it, either drawing it on paper, or at once modelling it, in small, in clay or wax. This preliminary step enables him to judge of the arrangement, and to correct and improve the general composition of his figure or group. He next proceeds to build up his statue of the desired size. The first thing necessary is to construct a sort of *nucleus*, or skeleton, by which the clay may be supported. This is made of wood or iron, according to the strength required, and the limbs are usually made movable, by attaching the skeleton parts to the main support, or trunk, by wire joints. The figure is then built up in clay; and whether it is ultimately to be draped or not, it should always be modelled naked, in order that the true forms may be easily distinguished, and the drapery made to fall naturally. In modelling in *relief*, a plane, or ground as it is called, is prepared, upon which the sculptor carefully draws his design. The clay is then laid and pressed upon this, the outline of the figures being bounded by the lines of the drawing. The projection or fulness of the forms must of course depend upon the fancy of the artist, or the purpose or situation for which the work may be intended. The same rule with respect to modelling the figures naked should be observed here as in figures or groups in the "round." To preserve the models from shrinking and cracking, it is necessary to sprinkle the clay occasionally with water; and on leaving them, to cover them over with damp cloths.

The next process is "casting." The model being completed, a mixture is made of plaster of Paris and water, which is thrown over the whole. When this is "set," or hardened, the clay within it is picked out, and there remains an exact mould of the model. This is washed, and the interior is brushed over with any greasy substance, usually a composition of oil and soap, to prevent the fresh plaster, with which it is next to be filled, from adhering too firmly to it. After the mould is thoroughly filled in all its parts with this plaster, mixed to about the consistency of cream, the latter is left to set. The mould is then "knocked off" with chisels, and a "cast" of the model is produced entire. If it is intended to execute the work in bronze, the same general principle is observed in the moulding; but there are particular processes to be attended to, in order to enable the mould to bear the weight of the metal, and to ensure the soundness of the "cast." [BRONZE.]

In copying a model in marble, the first step is to prepare two stones of the same size, or at least with an exactly corresponding graduated scale marked on the front of each, on which the block of marble and the model are respectively to be placed. The fronts of the two scales are so constructed or fitted up, that a "pointing" instrument can be applied to them. This instrument is usually composed of a pole or standard, to which a long brass or steel "needle"—capable of being extended and withdrawn, loosened or fixed, and moved in every direction by means of ball-and-socket joints—is attached. This is made to touch a particular part of the model. The whole instrument is then removed to the scale-stone on which the rough block is placed, and the marble is cut away till the needle reaches as far into the block as it had been fixed at upon the model. A pencil mark is then made upon the two corresponding parts of the model and block, and thus what is technically called "a point" is taken. This process is repeated till the numerous points at fixed depths, corresponding throughout with the surface of the model, are attained, and a rough copy of the sculptor's original work is thus mechanically made. These instruments for pointing marble statues are not always constructed in precisely the same manner. The practice of different sculptors has suggested various changes in detail, by which either the movement of the whole machine from one scale-stone to the other is facilitated, or a greater rapidity and security in taking points is attained; but the principle on which they act seems to be exactly similar in all. The statue being rudely blocked out or pointed, the marble is in this state put into the hands of a superior workman called a carver, who copies the minuter portions of the work, by means of chisels of various sizes, rasps, and files; the pencil marks or points showing him the limits beyond which he is not to penetrate into the marble. When the carver has carried the work as far as the sculptor desires, he proceeds himself to give it the finishing stroke, by retouching and improving the details of form and expression, by producing varieties of texture and surface, and by giving that general quality or appearance to the whole which constitutes what is termed harmony of effect.

SCURF is a material composed of minute portions of the dry external scales of the cuticle. These are, in moderate quantity, continually separated by the friction to which the surface of the body is subject, and are in due proportion replaced by others deposited on the inner surface of the cuticle. Sometimes, however, they separate in unnatural quantities, and this constitutes the disease called Pityriasis.

Pityriasis (from *πίτυρον*, bran) is a disease of the skin in which irregular patches of the cuticle appear covered with thin bran-like scales, or with particles of a fine white powder, which, as fast as they fall off, are succeeded by others. It may be regarded as a morbid excess of the natural process of desquamation which is constantly going on, and by which the old cuticle is removed from the surface of the body to be replaced by that of more recent formation. The commonest form of this disease is that called *Pityriasis capitis*, or dandriff. It affects chiefly the scalp and eye-brows, and is most frequent in children, in whom it originates either from generally disordered health or from mere neglect of cleanliness. It occurs also on the face and sometimes on other parts of the body in adults and old persons after exposure to the sun or a cutting wind, and it usually accompanies the commencement of baldness. The only local treatment which is necessary or useful is frequent washing, and the application of some mild and simple ointment.

In the other forms of pityriasis the discoloration of the cuticle is a more prominent sign than its desquamation in fine scales. *P. versicolor* occurs in the form of irregular yellow or light brown patches, which are chiefly situated on the front of the chest and abdomen, and are commonly called liver-spots or tan-spots. The extent and form which such spots present are infinitely various; but though they sometimes exist unaltered for several years, they rarely produce any inconvenience beyond a slight itching. *P. rubra* is an aggravated form of the preceding; the spots are more or less brightly red, and are the seats of considerable irritation. In *P. nigra* the essential part of the disease, which is of very rare occurrence, is the production of a cuticle of nearly a black colour.

SCURVY. This word, as well as its Latin synonym *scorbutus*, has been used very vaguely, both by medical men and by the public at large, to designate various diseases of the skin, often differing essentially from each other. Its derivatives, *scorbutic* and *antiscorbutic*, of which the former is employed to designate a supposed virus, the source of these diseases, and the latter the remedies employed for their cure, have been misapplied in a similar manner.

Scurvy, properly so called, is a malady of a peculiar nature, which occurs either at sea or on land as the result of various moral and physical causes of disease, especially of deficient nutriment and a scarcity or total deprivation of succulent vegetables or fruits. Its origin is involved in obscurity, and it is a question still debated whether it was known to the Greeks and Romans. Of its prevalence in the middle ages we have abundant testimony, but the frequent famines that resulted from the imperfect state of agriculture at that day gave rise to so many diseases, which, though different, yet had many points of resemblance, that we run considerable hazard of confounding them. Thus there is a great similarity between scurvy, the disease which was then called St. Anthony's fire, ergotism (the peculiar disease produced by spurred rye or other grain), and some of the pestilential fevers of the middle ages, both in their causes and symptoms, and there can be no doubt that the chroniclers of those times often mistook one for the other. It is customary to fix upon the year 1260 as the date of the first authentic mention of the malady, which then appeared in the Christian army during the campaign of St. Louis in Egypt. In the north of Europe, however, it would seem that scurvy has been known from the most remote antiquity, and until within the last two centuries it prevailed there endemically. With the improvements in gardening and agriculture, it gradually became less frequent. As late as the middle of the last century it was common not only among the peasants on the borders of the Baltic, but it prevailed in Scotland and in some of the sea-port towns of Devonshire and Cornwall, breaking out in winter, and disappearing as vegetable food became more abundant with the return of spring. Later the disease has occurred in camps, as in the French army of the Alps at the close of the last century; and in besieged towns whose inhabitants have been deprived of fresh vegetables. A famous French physician, M. Foderé, mentions that isolated cases occur every year in the more unhealthy quarters of Paris. Some of its earlier symptoms may occasionally be observed in patients admitted into the London hospitals; and our prison reports prove it to be by no means uncommon in persons sentenced to long periods of confinement. Diseases are still endemic in various parts of Europe, which present a great analogy to scurvy both in their causes and symptoms; such as the Radesyge in Norway, the Mal de la Rosa in the province of Asturias in Spain, and the Pellagra in Lombardy.

During the prevalence of the potato disease in Ireland, in 1845, scurvy prevailed extensively. It was occasionally observed at the same time in most of the large towns of England, and since, when potatoes have been scarce, it has been known to break out. During the Crimean war, it prevailed extensively, both among the French and English troops.

But it is at sea that the ravages of scurvy have been most severely felt, and any one at all familiar with the accounts of our early navigators must remember many heart-rending tales of suffering which they record. Even as recently as the time of Lord Anson scurvy was so fatal that during the first two years of his voyage he lost more than four-fifths of his original crew. The sagacity of Captain Cook however, only thirty years afterwards, suggested to him such means for the preservation of the health of his ship's company, that in a voyage of more than three years only one sailor of the Resolution died. The name of Captain Cook is now frequently mentioned in connection with his successful voyages, but his claim to the gratitude of posterity may be fairly grounded on the wonderful sanitary results of his voyage round the world.

The improvements which, at the suggestion principally of the late Sir G. Blane, were introduced into the victualling of the navy at the end of the last century, and especially the free employment of lemon-juice, have banished this disease from our navy, though it is still by no means infrequent in the merchant service.

The use of salt provisions has been very generally regarded as one of the most powerful exciting causes of scurvy. This notion, however, is not altogether free from error, for scurvy occurs even among those who never taste salted food. Such was the case with some of our troops quartered in the province of Adelaide at the Cape of Good Hope, among whom scurvy appeared in the year 1836. The men at that time had no hard duty to perform, and were supplied with fresh meat in abundance, but were deprived of vegetables. The annual occurrence of scurvy among the inmates of the lunatic asylum at Moorshedabad in India is an additional confirmation of the same fact. We may with more propriety refer the disease to the absence of vegetables than to any directly injurious effects produced by salt provisions.

The greatest attention to ventilation was not found during Lord Anson's voyage to diminish the severity of the disease; and this circumstance, coupled with other facts, such as the non-occurrence of scurvy in the ill-ventilated houses of the poor in London, warrants the conclusion that impure air is not an exciting cause of scurvy.

Some facts have led to the supposition that cold and moisture tend much to produce scurvy, but Dr. Budd, in his able treatise on scurvy, in the 'Library of Practical Medicine,' states that the men admitted with scurvy into the Dreadnought hospital-ship come almost exclusively from the Mauritius, India, Ceylon, or China. The non-existence of scurvy at Venice, and in other similar situations, proves that moisture alone cannot produce the disease.

It has been asserted, but never satisfactorily proved, that scurvy is propagated by contagion; an opinion which is now usually regarded as erroneous.

From all investigations, we may conclude that there is one condition which never fails to produce scurvy in persons, however various their situations may be in other respects, namely, a prolonged abstinence from succulent vegetables or fruits, or their preserved juices, as an article of food. But we are hardly warranted in asserting, as some men of eminence have done, that a deficiency of vegetable food is the only cause capable of producing scurvy. A disease very similar to scurvy, which used to attack the negroes in the West Indies, was attributed to their living exclusively upon bananas, and its cure consisted in changing their diet, and giving them fish and flesh to eat. Bad nutriment, of whatever kind, will, according to M. Foderé, sometimes produce the disease, and Dr. Henderson, a naval surgeon, recently stated in a medical periodical, that he has seen scurvy occur in persons who were taking daily doses of lemon-juice as a prophylactic against the disease.

From these facts Dr. Garrod was led to suppose that the real cause of scurvy was some deficiency in the food which was supplied by vegetable diet. Having examined the constituents of food that produced scurvy, he was led to conclude that such food was deficient in potash. Having analysed those vegetable foods which prevent and cure scurvy, as potatoes, water cresses, cabbages and lemon-juice, he found in all these a considerable quantity of potash. It is difficult to test this theory by withholding vegetable food and administering the salts of potash to patients afflicted with scurvy. It has, however, this characteristic of a true theory, that it explains the phenomena of the cure of scurvy by the addition of fruits or vegetables to the diet.

It was at one time supposed that the citric acid of the lemon-juice was the active cause of cure in cases of scurvy, and when this acid was separated it was substituted in the navy for the lemon-juice, but it entirely failed to arrest the disease.

Previous debility appears to predispose to scurvy, as does also an advanced age; the disease being rarest between twenty and thirty years of age, though it occurs more frequently between the fifteenth and twentieth year than in the succeeding ten years. The first symptoms of the affection are a change of the natural healthy complexion to a pale or sallow tint, accompanied with pains in the legs and loins, great languor and despondency, and indisposition to exercise. The gums soon become sore, apt to bleed on the slightest touch, livid and spongy. As the disease progresses the debility becomes greater, the slightest exertion inducing breathlessness and palpitation, and the complexion assumes a brownish or dingy hue. The gums become more livid, and swell more, so as sometimes to conceal the teeth, which drop out without undergoing decay. Hæmorrhage takes place from the lungs and from various internal organs, ecchymoses appear, and blood is effused under the skin in various parts, especially on the lower extremities and around the seat of any old injury. In the ham this effusion of blood is sometimes so considerable as to cause contraction of the knee-joint. Any wounds or ulcers put on an unhealthy appearance, and become covered with coagulated blood, and the slightest scratches degenerate into troublesome sores. In high degrees of scurvy, as in the case of Lord Anson's sailors, old wounds break out afresh, and a broken bone will become disunited, although the fracture may have been consolidated for some time. With these symptoms there is not so much derangement of the general functions as might be expected. The appetite usually continues good, though the patients are unable, owing to the state of their gums, to masticate their ordinary food; they sleep well, and the intellect is unaffected, though the spirits are much depressed. Scorbutic persons swoon readily, and not unfrequently die suddenly on making some more considerable exertion than usual.

If the disease should prove fatal, discoloured spots are found in many internal organs, while their tissue generally is of a paler colour than natural. The blood contains a less quantity of red particles than usual, but they are not dissolved in the serum, as some have supposed.

SCUTAGE. [Escuage.]

SCUTELLARIN. A bitter matter of unknown composition found in the *Scutellaria lateriflora*.

SCY'TALE (σκυτάλη, a stick) is the name of a secret mode of writing which was used by the ephors at Sparta in their communications with their kings or generals when abroad. The ephors cut the material upon which they intended to write into one long stripe, like a narrow riband, which they wound about a round staff so as to cover the whole. The command or communication which they had to send was then written upon it, and then the slip of writing material was taken from the staff and sent to the king or general. The slip appeared only covered with single letters, which none could read unless he wound the slip around a staff of precisely the same size as that used by the ephors. Kings and generals therefore, when they went abroad, were provided by the ephors with a staff precisely like that which the ephors themselves intended to use in their communications with them. (Plut., 'Lysand.,' 19.) This rude mode of sending a message must have originated at a very early period, but no instance of it is recorded previous to the time of Pausanias. (Corn. Nepos, 'Paus.,' 3.) After the Peloponnesian war, we find the Spartans using the scytale also as a medium through which they sent commands to their allied cities. (Xenoph., 'Hist. Gr.,' v. 2, 37.)

SCYTHE. The common scythe is an instrument too well known to require a minute description, but as much of its utility in agriculture depends on a correct adjustment of its parts, we shall briefly advert to them. The blade of the scythe, which is always curved, with the cutting edge on the concave side, is fixed to the handle at an angle both to the plane of the blade and to the tangent to the curve. It is on the nice adjustment of these angles that the perfection of the instrument depends. A scythe must cut the corn or grass, especially the latter, as near to the ground as possible; and where the land lies flat and the stones have been removed from the surface, a good scythe, in the hands of a skilful mower, will cut the grass so near to the ground that little or no stubble is left. Every farmer knows well that an inch of the grass near the ground adds more to the weight of the hay than several inches higher up, and that a skilful mower with a good scythe can easily add much more to the value of the crop than his earnings amount to, however liberally he may be paid, and that it is of the greatest importance that none but the best mowers be entrusted with the work, and that attention be paid to the form of their scythes and to their being frequently whetted.

It is the custom in England for the mowers to stoop much in mowing, by which they imagine that they have a wider sweep. The angle at which the handle is fixed is very acute to the plane of the blade. In other countries the mowers stand more upright, and a longer handle gives them a greater radius. Habit makes that position easier to which we have been long accustomed; but it is probable that a man can endure fatigue, and continue his exertion the longer, the more nearly his position is erect. In some countries the handle of the scythe is nearly straight, and the end of it passes over the upper part of the left arm. The position of the mower is then nearly erect, and his body turns as on a pivot, carrying the blade of the scythe parallel to the ground, and cutting a portion of a considerable circle. The position of the handle in this case must be such that when the scythe is in the middle of its swing, and the blade parallel to the ground, it rests naturally on the left arm above the elbow, while the mower is nearly in an erect position. By turning his body to the right, and stooping towards that side, he begins his cut, and by raising himself up, the muscles of his back greatly assist in swinging the scythe round.

The blades of the scythes on the Continent are mostly made of natural steel, such as is found in parts of Germany, and they are so soft that the edge can be hammered to sharpen it and keep it thin. In England the scythes are forged thin and well tempered, and to prevent their bending they have a rim of iron along the back to within a few inches of the point. This saves much time in sharpening, and they very seldom require the grindstone.

Most scythes have two projecting handles fixed to the principal handle, by which they are held, and these are variously put on, according to the fashion of the district. The real line of the handle is that which passes through both the hands and ends at the head of the blade. This may be a straight line or a crooked one, generally the latter, and by moving these handles up or down the main handle, each mower can place them so as best suits the natural size and position of his body. Hence it is that a man can seldom mow well with another man's scythe.

In mowing corn when ripe, which is an economical mode of reaping, the scythe need not have so great a sweep, nor is it necessary to cut the straw so near to the ground. The great difficulty here is to lay the cut corn evenly, so that the binders can readily collect it and tie it into sheaves. This is most effectually done by adding to the bottom of the handle a small hoop at right angles to the line of cutting, and by mowing always towards the standing corn, which is easily done by beginning at one end and going round toward the left in an irregular spiral to the centre of the field. The straw is thus laid leaning against the standing corn, and is readily collected with the arm by the binder, who follows the mower. As the straw is not always upright, but frequently bent to a side, this mode of mowing is not always practicable. When the corn is only slightly bent down, a scythe with an addition of a cradle, as it is called, collects the slanting straw more easily. The cradle is a species of comb, with three or four long teeth parallel to the back of the blade, and fixed in the handle. This inserts itself behind the straw to be cut, raises it up, and by a peculiar twist of the scythe after the stroke, it is left so as to be easily collected. Those who are accustomed to use the cradle-scythe do the work rapidly and well.

When the corn is much laid and entangled, it is impossible to use the common scythe, even with a cradle. This has probably suggested a scythe to be used with one hand, while a hook in the other gathers the straggling corn. The most perfect of these scythes is called the *Hainault scythe*, from a province of that name in Belgium, where it was first noticed. It is commonly used in different parts of the Continent. The Hainault scythe is swung by the power of the wrist principally. It does not cut the straw by so oblique a stroke as the common scythe, but rather as a bill-hook or axe would do, meeting the straw nearly at right angles. The hook collects a small bundle, which is severed at a stroke, and the left foot assists in holding what is cut and rolled together with the hook, in the hollow of the blade. It is thus laid aside, and fit to be tied up. This instrument is a great improvement on the English fagging-hook, which is used in the same manner, the left arm of the reaper acting the part of the hook; but as the handle is inserted in the plane of the blade, it causes the reaper to stoop low, which is fatiguing to the loins, especially of elderly people, who can more readily reap with the Hainault scythe.

The scythe is an instrument which should be more generally introduced in harvest, and experience has proved that it had many advantages over the sickle or reaping-hook. [HARVEST.]

SEA and OCEAN are terms by which the whole volume of water is designated which occupies the lower portion of the surface of our globe, and thus separates the solid and more elevated masses which are called land, and which rise above the level of the sea.

Sea-water has a salt and somewhat bitter taste, and in its natural state is unfit for drinking or for culinary purposes. Its specific gravity is about 1·0277, rain-water being 1·0000. The water of closed seas into which many rivers fall is lighter, as that of the Baltic, which is only 1·0067, and that of the Black Sea. But the water of the Mediterranean is more salt than that of the Atlantic Ocean. In those parts of the ocean which approach the poles the water is of less specific gravity than in those parts which lie towards the equator, which may be due to the melting of the enormous masses of ice which are found in the higher latitudes.

Sea-water has repeatedly been analysed; the latest results are stated under SODIUM. That of the Baltic contains only 1·18 per cent. of salt, but the water of the Mediterranean contains 4·18 per cent.; the former being considerably below and the latter somewhat above the average of the oceanic water. The sea is therefore a weak brine, from which the salt may be extracted by the heat of the sun and dryness of the climate.

Besides mineral substances, sea-water contains a slimy fetid matter, which imparts to it a nauseous taste, and which is probably the produce of the decomposition of animal and vegetable substances, which abound in the sea. It has been observed that the sea-water, when not agitated for a long time, is very subject to pass into a certain state of putrefaction, and in that state it exhales very unpleasant odours, which are a real nuisance to the seaman. It is likewise known that some low coasts between the tropics are subject to diseases, which are attributed to the miasma arising from the sea after a long continuance of calm weather.

It has often been maintained that sea-water has no colour, but it is well known that the sea at a great distance from the land has an exceedingly fine ultramarine tint, which cannot be considered due to reflection from the atmosphere, as the colour of the sea is frequently of a deeper hue than that of the sky, and does not change even when the sky is covered with clouds. This colour undergoes some changes in shoals, where it is modified by the colour of the matter which forms the bottom. The greatest variety in the colour of the sea seems to occur in the Greenland Sea, between 74° and 80° N. lat., where it varies from ultramarine to olive green, and from the most perfect transparency to deep opacity. The green colour is liable to changes in its position, but still it is always renewed near certain situations from year to year. According to Scoresby, from whom we take this account, it frequently constitutes long bands or streams, lying north and south, or north-east and south-west, but of various dimensions, sometimes extending two or three degrees of latitude in length, and from a few miles to ten or fifteen leagues in breadth. This occurs very generally about the meridian of London, and the whales chiefly feed in this green-coloured water. When examined by Scoresby, it was found to be replete with minute animals, principally Medusæ, to which its colour was due.

The transparency of the sea-water seems to be connected with its colour. It is much greater than that of river-water, which contains much heterogeneous matter in suspension. It has been said that the light penetrates to about the depth of 60 feet only, but this is a vague estimate, requiring much qualification; some rays certainly penetrate much deeper. This transparency of the sea-water increases with the distance from the shores, and is generally greater in the higher than in the lower latitudes, which may arise from the circumstance that the number of organic substances in the sea is much greater in warm climates. But there are many remarkable exceptions to the last-mentioned fact. Some parts of the sea between the tropics are distinguished by the transparency of their waters, especially the Caribbean Sea, where zoophytes and sea-plants, though growing on a bottom twenty or thirty feet deep, appear to be near enough to the surface to be plucked by a person in a boat; indeed some navigators affirm that the bottom of the sea may be seen at the depth of 150 feet. In the northern seas indeed it is asserted that the bottom may be seen at the depth of from 400 to 500 feet.

One of the most remarkable properties of sea-water is a certain luminous appearance, which has been observed in all seas, but appears in its greatest splendour between the tropics. In calm weather, when the water is moved by the motion of a vessel, the light assumes the form of brilliant stars, or round masses of a greenish hue, frequently eighteen inches in diameter. They float by the vessel in every part of the water which her bottom has touched, as deep as the lowest part of her keel, and form behind her a long and fiery train. At other times, when the breeze is strong, and the billows break and foam, the light appears like fields of flashing fire, through which the vessel is making her way. When the night is dark, the brilliancy of the water forms a beautiful contrast with the black concave of the sky; but as soon as daylight returns, the splendour disappears, and the sea exhibits only its usual dingy colour. At night, the slight agitation of the water occasioned by the action of a steady breeze upon the surface is generally sufficient for producing it. We are entitled to believe, as the result of modern scientific research, that this phosphorescence of the ocean depends exclusively on the presence of myriads of marine animals and animalcula, having the power of producing *animal light* (as animals higher in the scale of organisation produce *animal heat*);

unless, indeed, the conjecture of Professor Schönbein, that it partly arises from the oxidation of dead organic matter in the sea by means of ozone, should hereafter be verified. The luminous animals belong to every sub-kingdom of invertebrate animals: Protozoa; Radiata, especially the Acalephæ; Crustacea, as a class of Annulosa; Mollusca; and the osculent groups of the Annelida and Tunicata; some of the compound forms of the latter, or compound Ascidians, being among the most splendidly phosphorescent. In the Transactions of the Berlin Academy of Sciences is a valuable paper by Ehrenberg on the luminous animals of the sea, containing a copious list of the species observed to possess this property. [LUMINOSITY OF ORGANIC BEINGS, in NAT. HIST. DIV.]

From the well-known laws of gravitation, it is inferred that the surface of the sea is always at the same distance from the centre of the earth, and that consequently it forms a uniformly regular curve. This surface of course maintains the same level, and it is consequently the best basis from which to determine the relative elevations of the different parts of the land. Some facts bearing on this subject, and on the precautions requisite in the use of the sea-level as a *datum* line, are stated near the end of this article, where the physical changes of the sea are noticed. But though the surface of the sea is a regular curve, minute investigation has shown that there are some irregularities, and that some parts of the sea are more elevated than others. This is particularly the case with closed seas, which are generally more elevated than the ocean. The level of the closed seas is higher than that of the ocean when the mass of water brought to them by the rivers which discharge into their basin is greater than that which is lost by evaporation, and the straits by which they are united to the ocean are not wide enough to carry off the surplus waters quickly. On the other hand, when the evaporation is greater than the supply of water from rivers, the level of the closed sea sinks below that of the ocean, and it must be supplied with water from the latter by the straits which unite them.

The Baltic, though of no great extent, and though united to the open sea by three straits, one of which is of considerable width, receives so great a supply of river-water, that its level is higher than that of the North Sea. Very exact measurement has shown that this difference amounts to more than a foot between the level of the North Sea near the mouth of the river Eider and that of the Baltic near the town of Kiel. It is true that when the level of the North Sea has been raised by a continuance of western and north-western winds, a current sets from the Cattegat into the Baltic, but in calm weather it is always found that the current sets northward through the three straits. The difference of level between the Black Sea and the Mediterranean is much greater. The large rivers which fall into the Black Sea bring down an immense volume of water; and accordingly a very strong southern current is constantly found to be setting southward through the Strait of Constantinople into the Sea of Marmora. It generally runs with a velocity of about three miles an hour, which however at one place, called the "Devil's Current," is much greater, and at times between five and six miles per hour. The velocity of this current must vary with the seasons; for it is stated that the level of the Black Sea in winter is between two and three fathoms higher than in summer. The Sea of Marmora, which thus receives the surplus of the waters of the Black Sea, must also be more elevated than the Mediterranean; for the current which sets through the Strait of the Dardanelles is likewise constant and rather quick, though not so quick as that in the Strait of Constantinople.

The Mediterranean, on the other hand, receives a very scanty supply of water by rivers; for with the exception of the Nile, no large stream falls into its basin, which is of much greater extent than that of other closed seas, and therefore it must lose a great volume of water by evaporation. Halley showed that the Mediterranean, whose temperature is from 4° to 5° Fahr. higher than that of the Atlantic under the same latitude, must lose by evaporation nearly three times as much water as is brought into it by the rivers. The deficiency is supplied in two ways: by the current of the Dardanelles, which brings to it the surplus waters of the Black Sea and of the Sea of Marmora; and by that which sets through the Strait of Gibraltar from the Atlantic Ocean. The Atlantic current runs somewhat more than one mile and a half per hour. It has been supposed that, though this current constantly sets into the Mediterranean, an under-current runs in an opposite direction, carrying back a portion at least of the water to the Atlantic; but the attempts which have been made to establish this fact have failed, and it is probable that this supposed under-current does not exist. Notwithstanding the large supply of water which the Mediterranean receives at its two extremities, the level is below that of the Atlantic. Corabœuf found that the difference of level on the Mediterranean near Perpignan, and on the Bay of Biscay near Bayonne, amounted to nearly six feet; and Délambre and Mechain found it to be nearly three feet between the North Sea at Dunkerque and the Mediterranean near Perpignan.

In these instances the difference of level is satisfactorily explained; but the explanation is not so easy with respect to the great difference between the level of the Mediterranean and that of the Red Sea. These two seas are separated by the Isthmus of Suez, which extends about 70 miles from north to south. When the French occupied Egypt, they executed an extensive levelling across this isthmus; and the result was, that the Red Sea is above 32 feet higher than the Mediterranean. No river of importance, not even a perennial stream, falls into the Red Sea, which must also lose a considerable volume of water by evaporation. This loss of water is probably supplied by the current which sets into the Red Sea from the Indian Ocean; and some persons are of opinion that the difference of level between the Red Sea and the Mediterranean might be produced by this current. But it seems improbable that such an effect can be produced by this cause. According to Horsburgh and Wellsted ('Journ. of Lond. Geogr. Soc.,' vol. vi.), a current sets from the Indian Sea into the Red Sea between October and May, and it often runs with great rapidity. But between May and October the northern winds prevail through the whole extent of the Red Sea; and these winds, which frequently blow a gale, cause a continual current to set through the straits into the Gulf of Aden. Under such circumstances, it is evident that the sea must fall to its natural level, especially as this state of things continues for more than three months. Wellsted observes that in this season, from May to October, the reefs in the northern part of the Red Sea have about 2 feet less water on them than in the remaining months of the year. This therefore appears to be the whole extent of the difference produced on the level of the Red Sea by the current, which enters it through the Strait of Bab-el-Mandeb from October to May; but the French, as already observed, found the difference between the levels of the Red and Mediterranean seas to be not less than 32 feet. It would therefore appear that the Indian Ocean itself must be about 30 feet higher than the Mediterranean, and probably also higher than the Atlantic near the Strait of Gibraltar (see below) and that the difference of level in the different parts of the ocean is much greater than is commonly supposed. This is also proved by the difference of level between the Atlantic and the Pacific on both sides of the Isthmus of Panama. According to Lloyd ('Phil. Trans.,' 1830), the mean rise and fall of the Pacific two days after full moon is 21·22 feet, and in the Caribbean Sea 1·16 feet. The water at high-water mark in the Atlantic is 13·55 feet lower than in the Pacific. The mean between the high and low water in the Pacific is 10·61 feet, and in the Atlantic 0·58. It would therefore appear that the level of the Pacific is 3·52 feet higher than that of the Caribbean Sea, as at low-water, two days after full-moon, the Pacific sinks 6·51 feet below the level of the Atlantic; but it rises at high-water 13·55 feet above it.

In this comparison of the level of the two oceans, the Caribbean Sea is placed in opposition to the Pacific: but in reasoning from existing data and our present knowledge, we must admit that the level of the Caribbean Sea is much higher than that of the Atlantic near the old Continent. The north-eastern and eastern trade-winds force a great volume of water from the North Atlantic into the Caribbean Sea, and this is increased by another large volume of water which is brought to that sea by the Guiana current, and which enters it by the straits between the islands of Martinique and Trinidad. [ATLANTIC OCEAN, in GEOG. DIV.] Such volumes of water, being arrested by the long isthmus which separates the Caribbean Sea and the Gulf of Mexico from the Pacific, must produce a considerable accumulation of water along the western shores of those seas, and raise them above the common level of the Atlantic, and this fact is confirmed by the rapid current called the Gulf stream. [ATLANTIC OCEAN, in GEOG. DIV.] Opinion varies considerably as to the difference of level between the Gulf of Mexico and the Atlantic. Poussin found the level of the Gulf at the mouth of the river Suwanee 3·75 feet higher than that of the Atlantic at the mouth of St. John's River in Florida: but when Darby, in his 'View of the United States,' estimates the difference between the Gulf near the island of Cuba and the entrance of Chesapeake Bay as at least 83 feet, we must suppose that he has formed his opinion on erroneous data. Also, we cannot accede to the opinion of Humboldt, who, in comparing some barometrical observations made at Cumana, Cartagena, and Vera Cruz, with others made at Acapulco and Callao, came to the conclusion that in these parts the Pacific was about 9·5 feet lower than the Caribbean Sea and the Gulf of Mexico. Lloyd found the reverse to be the case at the mouth of the Chagres and at Panama, as we have mentioned above.

Mathematical investigation, founded on modern exact physical research, has however led to the discovery at once of a cause of difference of level in the sea, very different from any of the causes considered above, and of an example of that difference of the most interesting and instructive character. In the 'Philosophical Transactions' for 1859, p. 779-796, is a paper by Archdeacon Pratt, 'On the Influence of the Ocean on the Plumb-line in India,' which is a sequel to two former communications on the effect of Mountain Attraction on the Plumb-line in India. In this paper the author first describes the remarkable nature of the geographical position of Hindustan, consisting in this:—that the highest mountain-ground in the world lies to the north of it, and an unbroken expanse of ocean extends from its shores down to the neighbourhood of the South Pole. Now as water is lighter than land, that is, the quantity of matter contained in a given bulk of water is less than that contained in an equal bulk of land, the attraction or attractive power of the ocean is smaller than that of the land. A given bulk of land has a greater attractive power than an equal bulk of sea. Therefore, the sea on the shores of Hindustan is more attracted by the land than by the mass of the ocean beyond. The tendency of this, therefore, is to draw up the water to a higher level on the northern shores of the peninsula than at its southern extremity at Cape Comorin. But besides this, the mountain mass of Thibet and the Himalaya [PLAINS], presents a great excess of matter on the north, above that of the land of ordinary height, and consequently has a more powerful attraction, which is added to that of the land of Hindustan generally, in drawing up the sea to a greater height at the northern extremity of the peninsula than at the southern. Accordingly, it has been found by Archdeacon Pratt that the elevation of the sea-level at Kurachee, on the north side of the Arabian Sea, is 515 feet above that at Cape Comorin, and it must be about the same at the sandheads of Calcutta, at the north end of the bay of Bengal. Now the sea is our only standard of measurement to which the form of the earth can be referred. Regarding it as the general surface of the globe, all elevations above or depressions below that surface are, as we have seen, measured from it. But these 500 or 600 feet, fortunately, are the greatest extent to which the sea-level can be affected, as there is no part of the globe where the attraction on one side, and the deficiency of attraction on the other, can be so great as in that particular portion of the world where this difference exists.

The bottom of the sea is similar to the surface of the land as to the irregular succession of elevations and depressions, and it is diversified by mountains and valleys and plains of different elevation. The summits of the submarine mountains rise above the level of the sea in the form of islands. In several parts large table-lands are found, whose surface is not at a great depth below the level of the sea: when their surface is covered with sand, they are named sand-banks; and when it consists of coral rocks, coral-banks. Near the edges of these banks the depth of the sea is generally very great. Some of the summits are barren, others are covered with vegetation, but all teem with life of one order or other. The most extensive formation of the submarine table-lands occurs in the North Atlantic. Its most north-eastern portion is formed by the Outer Bank and the Great Bank of Newfoundland. [NEWFOUNDLAND, in GEOG. DIV.] West of the Great Bank of Newfoundland are Whale Bank, Green Bank, Banquereau, and Mizen Bank. The three last-mentioned banks are situated in front of the entrance of the Gulf of St. Lawrence. Opposite the coasts of Nova Scotia are Sable Bank and Le Have Bank; and then follow, in the same south-western direction, St. George's Bank, or the banks of Nantucket, which approach the continent of North America in the vicinity of New York. From this point the banks occur at a short distance from the shores of the United States, and extend, almost without interruption, to Cape Florida and Sable Point, the most southern extremity of the peninsula of Florida. West of this peninsula is the Tortuga Bank, the continuation of which skirts the shores of the United States in the Gulf of Mexico as far west as the mouths of the Mississippi. This series of banks occupies more than 1400 miles in length; but there is always water enough on them for the largest vessels, with the exception of the Virgin Rocks on the Great Bank of Newfoundland, and the shoals of St. George's Bank. In all the other parts the least depth is not less than ten fathoms, and in general forty fathoms of water are found on them. The surface of these banks is very level. Along the northern and north-western edge, which lies opposite to the coast of America, the depth suddenly descends to 100 fathoms, and along the southern edge to 300 fathoms. The descent from the edge of the bank to the deep sea is nearly perpendicular. The banks, especially those north of 40° N. lat., are frequented by immense shoals of fish, especially cod.

The Columbian banks, under which name are comprehended all the banks which begin opposite the eastern shores of the peninsula of Florida and extend in a south-eastern direction to the Mona Passage between Haïti and Puerto Rico, are divided from the North American banks by the Florida Gulf-stream. They consist of two larger banks, called the Little and Great Bahama Bank, which occupy the north-western portion of the group, and of five smaller banks, which occur at great distances from one another in a south-eastern direction. These banks have from 15 to 20 fathoms water on their edges, but they are beset with rocks and numerous shoals, of which a few are dry at low-water: they are therefore shunned by vessels. The surface of the banks consists of coral, covered with an accumulation of shells and calcareous sand. On their eastern edges, along the Atlantic, are the Bahama Islands.

Of the smaller banks which occur in the Atlantic we shall only mention the Bank of Arguin, which lies near the western coast of North Africa, beginning at Cape Blanco (21° N. lat.), and extending to the neighbourhood of Portendik (about 18° N. lat.). It is dangerous for navigators, as there are many parts in which the water is not deep enough for large vessels, many of which have been lost on it. The Abrolhos, near the coast of Brazil, between 16° and 18° S. lat., is not extensive, but it is extremely dangerous on account of the soundings being very irregular, varying between 36 and 4 fathoms. In two successive casts of the hand-lead the soundings frequently vary from 30 to 10, and sometimes even to 4 fathoms.

There are several banks in the Indian Ocean: the most extensive are the Saya de Malha and the Bank of Nazareth. The Saya de Malha extends in length from north to south between 8° 18′ and 11° 30′, and is cut by 61° 30′ E. long. The surface is uneven, and in many places there are not more than between 6 and 10 fathoms water: it consists of corals and shells. The most southern extremity of the Nazareth bank consists of the islands called Cargados, in 16° 47′ S. lat. and near 60° E. long. From this point the bank extends in a north north-east direction to 14° S. lat. The surface is tolerably level, and the least depth of water does not fall short of 14 fathoms.

An extensive bank, called the Needle or Agulhas Bank, surrounds the southern extremity of Africa. It extends towards the west beyond the Cape of Good Hope, and towards the east beyond Cape Padrone, east of Algoa Bay. As it is not divided, like the other banks, from the continent by a tract of deeper water, it is not to be considered as a table-land, but as a submarine prolongation of the continent. Between Cape Agulhas (10° E. long.) and Cape Vaccas (22° E. long.), it extends to 37° S. lat., or to a distance exceeding 150 miles from the continent. The depth of water on this bank varies between 30 and 90 fathoms. The surface is composed of coarse sand, corals, shells, and small stones. Along its western edge it is skirted by a mud-bank, which is covered by water from 50 to 120 fathoms deep. The structure of the land is thus continued into the sea, beyond the extremities of continents, in other parts of the world also; as in the islands of Tierra del Fuego at the termination of South America. In other cases, as on the coast of Norway, there is a rapid and complete cessation of the high ground in the course of a very small distance from the shore.

There are numerous banks in the Pacific, especially south of 20° N. lat. All the larger banks are surrounded by coral reefs, on which islands of small extent often occur. [REEFS.] Near banks, the sea usually deepens to 200 and 300 fathoms, and even more.

The subject of the depth of the sea in general next claims our attention. We are best acquainted with the depth of several close seas, especially those which are much navigated. The depth of the Baltic is inconsiderable; it usually varies between 30 and 40 fathoms, and only in two or three places sinks below 100 fathoms. The North Sea is somewhat deeper in its northern part. Between the Shetland Islands and the coast of Norway the depth varies between 80 and 140 fathoms, but it gets gradually shallower towards the south. In the Straits of Dover the deepest place is only 26 fathoms. The depth of the English Channel increases as we proceed towards the west, but very slowly. East of the Eddystone it does not exceed 50 fathoms. The Irish Channel is in general deeper. Though there are some places between Wales and Ireland in which it does not exceed 40 fathoms, its general depth may be said to vary between 60 and 80 fathoms; and in the strait between the county of Antrim and that of Wigton in Scotland it attains 100 fathoms. The Mediterranean is much deeper than the Baltic and North Sea, more especially along the southern coast of Spain and about the island of Sardinia, where the depth varies between 500 and 1000 fathoms; but the deepest parts appear to be in the spaces devoid of islands to the west of Sardinia, and to the east of Malta, where the depth is about 1760 fathoms, or two miles. A shallow tract extends from Trapani in Sicily to Cape Bon in Tunis: it is called by the Italian sailors *scherchi*, and is of inconsiderable but very variable depth. That portion of the Mediterranean which lies east of this shallow tract is not so deep as the western part. The Red Sea may be compared in depth with the eastern part of the Mediterranean. [RED SEA, in GEOG. DIV.] The sea which surrounds the islands of the western gulf of the Indian Archipelago seems nowhere to sink much below 50 fathoms, and these islands, in fact, belong to the continent of Asia; but on the coast of Northern Borneo, in the Straits of Lombrok, and near the middle of the Strait of Macassa, commences, southward and eastward, a very deep sea hitherto unfathomed.

The main body of the sea has a much greater depth. In most parts of the Atlantic, where the sea has been sounded, no bottom was found with 300 fathoms. Between Europe and America the bottom seems to offer great inequalities, being furrowed by deeper tracts, which run north and south. In the North Atlantic are the greatest depths at which the bottom of the sea has been reached; the places where it has been fathomed, according to Maury, are not deeper than 25,000 feet, or about four miles and three quarters. The deepest place in this ocean is probably between the parallels of 35° and 40° N., and immediately to the southward of the Grand Banks of Newfoundland. The small general depth of this part of the Atlantic has given rise to the opinion that the sea round the North Pole is not so deep as that which surrounds the South Pole, but this opinion has no foundation. Phipps and Scoresby sounded in several places between Spitzbergen and Greenland with from 780 to 1200 fathoms, without finding a bottom; and Ellis and Ross did the same in Hudson's Bay and Baffin's Bay. In the Pacific Ocean the depth seems also to be very considerable, but few soundings have been made there.

The depth of the sea near the land varies with the nature of the shores. Where the country near the sea is elevated, and terminates in high and rocky shores, the sea is generally of considerable depth, as in the fiords of Norway. Such shores have generally good and safe harbours. But when a low plain terminates on the sea with a flat sandy bank, the sea is shallow and frequently continues to be so to a great distance from the shore. In many places such shores are inaccessible even to boats, and vessels must keep at a distance of many miles. Such shallows consist either of sand or of mud. These low shores are generally destitute of harbours, or at least they occur only at great distances, and much expense is required to maintain them in an efficient state: the harbours on rocky coasts are not subject to this inconvenience.

It is a very remarkable phenomenon, which has not yet been satisfactorily explained, that the temperature of the sea decreases as the land is approached, and it also decreases on shoals and banks; and as this decrease may be detected by the thermometer at a considerable distance from land, this instrument is now used for the purpose of ascertaining the approach to land or the presence of shoals. It must, however, be observed, that though this decrease generally takes place, it is not universal.

As late as the end of the last century it was a generally received opinion that the whole mass of sea-water, from the surface to the bottom, had the same temperature in the same latitude. But numerous observations, which have been more recently made, have shown the inaccuracy of this assumption. It has been found that the law which is constant for the earth must be inverted for the sea. The farther we descend into the interior of the earth, the higher is the temperature; but the deeper we dip into the sea, the lower is the temperature of the water. But this does not take place in the same ratio in the whole sea. Captain Ross found the temperature of the sea in Baffin's Bay, 3900 feet below the surface, + 25·52°, while the surface itself was + 33·80. Beechey, in 47° 18′ N. lat., at a depth of 5124 feet, found the water + 39·56°, and at the surface it was 46·22°. Sabine found that the water in the Caribbean Sea, at a depth of 1000 fathoms, had a temperature of 45·50°, whilst at the surface it was 83·30°. According to an observation of Franklin, the water at a depth of 650 fathoms, in 57° 44′, was 40·5°; at 450 it was 41°; and at the surface, 45°. There are a few instances in which a new increase of the temperature has been observed at a very great depth. In the following observations made by Beechey, in the Pacific, the temperature became stationary at a great depth:—

23° 28′ N. lat.		*58° 48′ N. lat.*	
Temp. at the surface	63°	Temp. at the surface	54°
At a depth of 300 ft.	62°	At a depth of 600 ft.	45°
At a depth of 900 ft.	50°	At a depth of 1200 ft.	41°·5
At a depth of 1260 ft.	47°·5	At a depth of 1962 ft.	40°·5
At a depth of 1860 ft.	47°·5	At a depth of 2652 ft.	40°·5

As a proof of the increase of the temperature of the sea at a great depth, we copy the following observations, of which the first two were made by Beechey, and the last by Prescott; the first in the Pacific, and the last two in the Atlantic Ocean:—

14° 22′ N. lat.		*55° 58′ S. lat.*	
Temp. of the air	91°	Temp. of the air	37°
Of the sea at its surface	88°	Of the sea at its surface	43°·5
At a depth of 600 ft.	57°	At a depth of 600 ft.	42°·5
At a depth of 1200 ft.	55°	At a depth of 1380 ft.	42°·5
At a depth of 1800 ft.	48°·5	At a depth of 1950 ft.	40°·5
At a depth of 2400 ft.	49°·5	At a depth of 2580 ft.	41°·5

13° 22′ N. lat.			
Temp. of the air	83°	At a depth of 540 ft.	57°
Of the sea at its surface	82°	At a depth of 660 ft.	58°
At a depth of 180 ft.	71°	At a depth of 720 ft.	58°
At a depth of 360 ft.	61°	At a depth of 1320 ft.	60°

The renewed increase at a great depth is a very difficult problem to solve: it is possible that it may be owing to submarine currents of different degrees of temperature, as some have supposed. Sir James C. Ross ascertained, by seven different experiments, that between the parallels of 55° and 58° 30′ S., there is a belt encircling the earth, where the mean temperature of the sea, that of the greatest density of its water, or + 39·5°, prevails throughout its entire depth, forming a neutral border between two great thermic basins of the ocean.

But there are facts on record which clearly show that in certain parts of the ocean there must exist some agency by which the water acquires a higher degree of temperature than might have been expected from ordinary causes. Horner, in Krusenstern's 'Travels,' observes that, in some places in the Gulf-stream, the hand-lead, when it had descended to a depth of between 480 and 600 feet, was heated to such a degree that it was impossible to take it into one's hand. A still more remarkable anomaly is presented by the temperature of the sea between Greenland and Spitzbergen. In nearly every trial, Scoresby found that this sea, at a depth of from 100 to 200 fathoms, was from 6° to 7° warmer than at the surface; and Franklin states that when he accompanied Captain Buchan in his expedition to the North Pole, the water brought from any great depth was invariably found to be warmer than that of the surface. Some persons are of opinion that the melting of the great masses of ice, by which that sea is surrounded and partly covered even in summer, may have had the effect of cooling the surface. But this is contrary to the well-established law that the colder water, being the denser, sinks to the bottom, and the warmer rises to the surface; and further, it may be asked why Ross and Parry, in navigating Davis's Strait, Baffin's Bay, and Hudson's Bay, where the masses of ice are neither less numerous nor less extensive, always found the contrary to take place.

The important subjects of the distribution of temperature in the atmosphere over the sea, and of the mutual relations of the temperature of the two elements, will be considered in the article TEMPERATURE, TERRESTRIAL, DISTRIBUTION OF.

Masses of ice surround the two poles. The cause of this has been thus generalised by Sir J. F. W. Herschel:—"Beyond the 56th parallels of latitude, the temperature of the water is lower at the surface, and rises as the thermometer descends, till the level of 39° [or the temperature of greatest density] is reached. The sea, then, even in deep water, becomes frozen at the surface in the winter months, or rather through all that portion of the year which intervenes between the beginning of September and the latter end of June; July and August being, in high latitudes, the only open months. . . . . . There can be very little doubt that, in the winter time, the surface of the ocean at both poles is entirely frozen; but at the North Pole it is probable, from many indications, that open water exists over a very large area of the central polar basin during a considerable portion of the warmer months." Some of these indications are then stated, but a fuller view of them will be found in Sir John Richardson's 'Polar Regions,' pp. 222-231.

It was formerly conjectured that the mass of ice inclosing the North Pole extended to the vicinity of 81° N. lat., because all navigators who had attained that latitude agreed in stating that the ice there rose to a great height, and stood firm like a wall. This general opinion gave rise to the attempt of Captain Parry to reach the pole by travelling on this ice, which was supposed to be immovable. But Parry was soon aware that he was travelling on ice which was in continuous motion, being carried by a current towards the south and south-west, and this circumstance occasioned the failure of the undertaking. When he had advanced, according to his calculation, several miles to the northward in twenty-four hours, he found, on observing the altitude of the sun, that the motion of the ice had carried him as far southward, and that for several days he had advanced very little nearer to his object. He was obliged to abandon the attempt, after having reached 82° 40¼′ N. lat. Thus we have learned that the exterior parts of the great mass of ice supposed to inclose the poles consists of moving masses, which lie close together, and are only occasionally divided from one another by narrow straits. The pieces of ice which detach themselves from this great accumulation and enter the open sea are called *heavy drift-ice*. The larger pieces of ice of this description are a mile in length and breadth, and upwards of 30 feet in thickness; but others are of less dimensions. The farther they advance southward, the more their dimensions are reduced by the action of the sun and of the water. But there are two other descriptions of ice-masses in the sea, which appear to have a different origin—the ice-fields and the icebergs. The term *ice-field* is applied to sheets of ice so extensive that their limits cannot be discerned from the mast-head. They often occur of the diameter of 20 or 30 miles, and, when they are very closely united, they sometimes extend to the length of 50 or 100 miles. Their average thickness may be from 10 to 15 feet, and their surface is mostly level, except where *hummocks* or low ice-hills occur, and then the thickness is often 40 and even 50 feet. These hummocks are produced by two fields coming into contact, when their broken edges are raised by the violent concussion, and thrown upon the fields themselves. These hummocks, therefore, are usually situated near the edges of the field. In some fields the hummocks form ridges or chains; in others they consist of isolated peaks. The smaller fields, or those whose extent can be seen from the mast-head, are called *floes*. The surface of these masses of ice, before July, is always covered with a bed of snow from a foot to a fathom in depth; this snow dissolves in the end of summer, and forms extensive pools and lakes of fresh water. The great extent and the level surface of the fields show that they cannot be portions of the ice over which Parry travelled. It is therefore supposed that they are generated in the sea which lies between Greenland and Spitzbergen, and which, though navigable during the summer, is covered with a continuous sheet of ice in the colder season. The fields appear to be the parts of this great sheet, formed by its breaking up at the approach of summer. When, on the further advance of the season, the field-ice and floes of the general surface break, the ice becomes heaped together in sheets confusedly piled on each other, into what is called *pack-ice*, or an *ice-pack*. The pellicle of ice formed over great areas of the polar seas, as the immediate effect of a general depression of temperature below the freezing-point of sea-water, is called *pancake-ice*. It is, in fact, the beginning of the production of ice in the ocean; and the possibility of its existence, as well as that of all continuous masses of ice, depends on the property of regelation, to which Faraday has recently called attention [ICE; WATER], and which Tyndall has applied with so much success to the elucidation of the phenomena of glaciers, the parents of *icebergs*, to which we must now proceed. These are immense masses of ice rising to a great height above the level of the sea; some of them attain a height of 100 feet above the surface of the sea, and a few have been found which seem to be more than twice that height. Their base near the sea-level is not extensive, the larger masses generally being not more than 4000 feet in circumference, though Middleton states that he saw one which was from three to four miles in circuit. The most common form of the iceberg is for one side to rise perpendicularly to the very summit, the opposite side being very low, while the intermediate surface forms a gradual slope. Some have regular flat surfaces, but frequently they present a great variety in form and appearance. Some of them resemble palaces, or churches, or old castles, with spires, towers, windows, and arched gateways; while others resemble pyramids and obelisks, and others are like ships, trees, animals, and human beings. When a number of them are near one another, which frequently happens, they present the appearance of a mountainous country. When seen from a short distance, they look like huge hills of marble; and when the sun shines on them, they glitter like silver. Sometimes earth, gravel, and sand may be observed in them. Their prevailing colour in the fresh fracture is greenish-gray, approaching to emerald-green. This colour resembles that of the glaciers of Switzerland [GLACIERS, in NAT. HIST. DIV.], and the icebergs are masses broken off from glaciers, or from barrier lines of ice-cliff. They are rarely met with in the sea between Greenland and Spitzbergen, because in these parts only a few glaciers approach near the water's edge. But on both sides of Davis's Strait and Baffin's Bay, and also on the eastern shores of Greenland as far north as 70° N. lat., glaciers cover the land, and in many places advance to the shores of the sea. In some places they terminate in a precipitous edge on the coast. It is only in the sea which surrounds these coasts that the icebergs are numerous. They seem to owe their origin to the circumstance of glaciers being in a continual state of progress. The glaciers of Greenland, which are situated on the margin of the sea, protrude their exterior parts over the ocean, and in summer, when the ice becomes brittle, the force of cohesion is overcome by the weight of the prodigious masses that overhang the sea, and they are detached from the glacier with a dreadful crash. Thus an iceberg is formed. These icebergs, as it seems, are most common along the eastern shores of Greenland, and at the distance of 15 to 20 miles from the coast, where they occur by hundreds and thousands, forming a sort of barrier outside the drift-ice which is near the shore, and preventing its removal by an off-shore wind. Captain Graah states that this barrier of icebergs renders it impossible for vessels to approach these shores.

These masses of ice render navigation very dangerous; and the ice-fields especially have caused the loss of many whaling-vessels. These extensive masses are frequently put into a rotatory movement by a cause which has never been discovered. When thus whirled about, their outer edges acquire a velocity of several miles per hour. A field thus in motion, coming in contact with another at rest, or with one that has a contrary direction of movement, produces a dreadful shock. The strongest ship is a mere atom between two such masses of matter in motion, and many vessels have thus been destroyed. The ice-fields are particularly dangerous in foggy weather, as their motions cannot then be distinctly observed. Icebergs are much less dangerous, partly on account of the small space which they occupy when compared with ice-fields, and partly because they are easily distinguished at a distance in the night by their natural brightness, and in foggy weather by a peculiar blackness of the atmosphere. As, however, they occur far from land and often in unexpected situations, sailors when crossing the Atlantic between 50° and 60° N. lat., or even farther to the south, must always be on the watch for them in the night time. Occasionally the whale-fishers derive some advantage from them. As they sink deep into the sea, they are very little affected by the wind, and they furnish secure mooring to a ship in strong adverse winds, or when it is required for other purposes. But mooring to lofty icebergs is attended with considerable danger. Being sometimes very nicely balanced, they are apt to lose their equilibrium; and vessels have often been staved and sometimes wrecked by the fall of their icy mooring, while boats have been overwhelmed even at a considerable distance by the swell occasioned by such a catastrophe. Water is sometimes procured by whaling-vessels from the deep pools of water that are formed in the summer season on the depressions in icebergs, or from the streams which run down their sides.

On approaching a field or any compact aggregation of ice, the *ice-blink* is seen whenever the horizon is tolerably free from clouds, and sometimes even under a thick sky. It consists of a stratum of lucid whiteness, which appears over the ice in that part of the atmosphere which joins the horizon. A clear sky presents a beautiful and perfect map of the ice, 20 or 30 miles beyond the limit of direct vision, but less distant in proportion as the atmosphere is more dense and obscure. Each kind of ice has a different blink. Field-ice has the most lucid blink, accompanied with a tinge of yellow; that of packed ice is more purely white; and ice newly formed upon the sea has a grayish hue.

According to the experiments of Scoresby, the specific gravity of the ice, when compared with that of sea-water occurring in the Greenland Sea, at the temperature of 35° was ascertained to be from 0·894 to 0·900. That part of the ice, therefore, which is above the surface appears to be, to that below the surface, in the proportion of 1 to between 8 and 9. For every solid foot of ice which is seen in a mass floating in the sea, there must be 8 or 9 feet below. Hence it sometimes happens that large icebergs, when they are carried into shallow water, take ground, and remain stationary for one or two years, until so much of their volume has been wasted by the action of the sun and of the atmosphere, that they begin to float again.

It excited some surprise when it was discovered that the ice floating about in the sea consisted of fresh water. It is true that it generally contains a very small portion of salt, but it is probable that this small portion of salt is derived from the salt water contained in the pores of the ice. If, says Scoresby, in confirmation of this opinion, the newest and most porous ice be removed into the air, allowed to drain for some time in a temperature of 32° and upwards, and then be washed in fresh water, it will be found to be nearly quite free from salt, and the water produced from it may be drunk. According to the Russian explorer, Baron Wrangell, whenever the surface of the ice on the north coast of Siberia is clear of snow, the salt may be found deposited in crystals; and in the neighbourhood of the *polynias*, or interior open seas of the Arctic regions already mentioned, the layer of salt is often of considerable thickness. All this is in conformity with the fact, first definitely ascertained by Dr. Faraday, that in the process of freezing the foreign bodies contained in water are separated from it; agreeably to a principle which appears to be manifested in the crystallisation of most if not all fluids, of the separation of heterogeneous matter. On account of the salt contained in it, sea-water does not, like pure water, freeze at the temperature of 32°, but in the Greenland Sea, where its specific gravity is 1·0263, it begins only to freeze at 28½°.

There is not any portion of the surface of the sea which is not subjected to some kind of motion, and this circumstance must tend greatly to preserve its purity. The water in some parts of the sea is always propelled in the same direction by the currents. [ATLANTIC OCEAN; PACIFIC OCEAN, in GEOG. DIV.] Nearly the whole sea is four times in the day subject to a change in its level by the movements of the tides. The motion produced by the winds, and known by the name of waves, is much less regular. Each wave presents a gently ascending surface to the windward, and a perpendicular descent leeward. The elevation of the waves varies according to the strength of the wind. A rather heavy gale raises them from six to eight feet above the common sea-level; but in very strong gales they attain an elevation of thirty feet. This motion of the surface of the sea is not perceptible to a great depth. In the strongest gales it is supposed not to extend beyond 72 feet below the surface, and at a depth of 90 feet the sea is perfectly still. The form and even the size of the waves vary according to the depth and the extent of the sea. In shallow water, where the lower part of the waves approaches the bottom, and meets with resistance, the waves are abrupt and irregular, and this is also the case in confined seas; whilst on the open ocean they are wide and long, and rise and fall with great regularity. When the waves run to a low shore, the slope of the ground breaks their force, and they terminate in a tranquil manner; but when they are impelled against an elevated rocky coast, being repelled by the rock, they produce what is called a *surf*. This violent rising of the sea on a rocky coast sometimes attains an elevation of 100 feet above the sea-level. The surf is always dangerous to pass, except in boats of a peculiar construction. The waves do not subside simultaneously with the wind. The momentum of the water preserves the sea in its agitated state for many hours. The air being little agitated, or not at all, is unable to depress the undulations of the sea, and therefore the waves during a calm after a gale rise higher, and their most elevated part forms a more acute angle than during the gale. Such a state of the sea is called a *hollow sea*. [WAVE.]

The term *Ocean* (a Greek word, Oceanus, Ὠκέανος) is applied in a general and somewhat indefinite manner to distinguish the greater areas of sea. The word first occurs in Homer, who uses it to designate the river or stream which, according to his ideas, surrounded the surface of the earth like a circle. The Greek geographers, however, knew that the ocean was a wide expanse of water, which surrounded the land, and the term ocean was used by them in this sense. They supposed that it penetrated deep into the mass of the continent by four great bays or seas: these were, on the south the Arabian Sea and the Persian Gulf; on the west the Mediterranean; and on the north an imaginary strait which connected the Northern Ocean with the Caspian Sea. (Strabo, p. 121; Pomp. Mela, i. 1.) [GEOGRAPHY.]

The actual surface of the globe may be reckoned at about 197,000,000 of square British statute miles; of which 145,000,000 are covered by the waters of the ocean—now using this term in its widest and most emphatic sense, as meaning the entire collection of seas—while the area of the land is about 52,000,000 of miles; the proportion of land to sea being thus as about 1 to 3, the land occupying one-fourth, and the sea three-fourths of the entire surface of our planet. The latter, however, is so unequally distributed that there is three times more land in the northern than in the southern hemisphere. The torrid zone is principally occupied by sea, and only one-twenty-seventh part of the land on one side of the earth has land opposite to it on the other. Sir John Herschel has recorded, that "one result of maritime discovery on the great scale, is, so to speak, *massive* enough to call for mention as an astronomical feature" of our planet. "When the continents and seas are laid down on a globe (and since the discovery of Australia, and the recent addition to our Antarctic knowledge of Victoria Land by Sir J. C. Ross, we are sure that no very extensive tracts of land remain unknown) we find that it is possible so to divide the globe into two hemispheres, that one shall contain *nearly all the land*; the other being almost entirely sea. It is a fact, not a little interesting to Englishmen, and, combined with our insular station in that great highway of nations, the Atlantic, not a little explanatory of our commercial eminence, that London occupies nearly the centre of the terrestrial hemisphere." He adds that "more exactly Falmouth," the most westerly port of Great Britain, occupies this centre. "The central point of the hemisphere which contains the maximum of land," he continues, "falls very nearly indeed upon this port. The land in the opposite hemisphere, with the exception of the tapering extremity of South America and the slender peninsula of Malacca, is wholly insular, and were it not for New Holland would be quite insignificant in amount." 'Outlines of Astronomy,' par. (284). Another illustrative view of the distribution of land and water has been given by Professor Ansted. In the space between the Equator and the Antarctic Circle (consisting of the southern half of the Torrid Zone and the whole of the South Temperate Zone) which occupies 90,000,000 of square miles, nealy 77,000,000 (almost seven-eighths of this space) are water, while in the North Temperate Zone the quantity of land is nearly equal to that of water. As the great depressions on the solid surface, occupied by the principal part of the water on the globe, are connected together by comparatively narrow passages, and are therefore really united, forming one wide and continuous expanse of sea, the emphatic application of the term ocean, in the singular, is as obviously correct in modern science, as it was in its original use by the Greeks. But notwithstanding this unity, the different parts of the ocean are known by distinct names, the most important being the Pacific, the Atlantic, Indian, Arctic, and Antarctic oceans. There are also some internal seas of considerable extent, as the Mediterranean, the Baltic, and others, which are almost entirely inclosed by land, and, like the ocean, are filled with salt-water; besides the isolated Caspian and Sea of Aral, and also the great gulfs and penetrating bays of North America, together with others, better known, but far less extensive, in Europe.

In considering the *Physical Changes of the Ocean*, we find that the relations of sea and land in respect of area, height and depth, interchange of moisture, aërial currents, and many other circumstances which influence mechanical, chemical, and vital phenomena on our globe, are so important, and, within the compass of the few hundreds or thousands of years which belong to history or tradition, appear to have suffered so little change, that nothing short of the complete proof furnished by geology ought to satisfy our minds that every one of the conditions which make up the now harmonious mutual dependence of land and sea is variable, that the present aspect of the globe is but one term of a long series of successive transformations, the law of which—the great problem of geology—is perhaps not beyond the reach of observation and induction. But as we proceed in this inquiry, we learn the important lesson that the present history of any of the great elements of terrestrial nature is imperfect, cannot in fact be ascertained, without the light derived from its past history, of which it is the continuous production. The sciences of Geology and Physical Geography are thus found to be parts of each other, alternately, according to the aspect in which they are viewed. Nearly all aqueous geology, or the knowledge of the deposition of the fossiliferous strata, consists in investigating the physical changes of the sea during past ages of the earth's history, of which the changes it is now undergoing are the ever-proceeding completion.

Are the relative areas of sea and land constant? To this geology replies, that what is now land was formerly the sea; that in some of the parts which are now covered by water land anciently existed, so as to pour down rivers, conveying sediments of different sorts through valleys and plains clothed with various vegetation. The land which we behold is the bed of the ancient sea; or, to speak more precisely, it is composed of the dried indurated sediments and the cooled volcanic products which, during long intervals of time, were accumulated beneath the ocean. Whether, during the process by which the ancient sea-bed was raised to constitute our now dry land, a proportionate area of what was formerly land was depressed to constitute the modern sea-bed, is an unsettled question; but it is clearly proved that if any proportion of areas between sea and land is a necessary condition of our globe, all the parts of these areas are displaceable and have been displaced.

Is the relative level of the land and sea constant? We cannot affirm it. We cannot deny the existence of causes which may change generally and continually this relation, any more than the operation of agencies which locally and at intervals are known to derange it. If there be a general change of temperature in the earth itself, or communicated from the planetary spaces around it, or occasioned by any condition affecting the radiation of heat in the atmosphere above it; the unequal influence of this change on the unequally expanding and contracting liquid and solid masses will necessarily occasion variations in the relative level of sea and land. Now, geology appears to have established many facts regarding the fossil organic remains of plants and animals, which admit of no clear general explanation except by supposing extensive, perhaps general changes of climate. There is nothing positively known which forbids the belief that such changes may be still really, however slowly, in progress; there is abundant proof of innumerable local derangements of the level of land and sea in comparatively modern geological, historical, and even very recent periods, and a slow upward movement of land is actually traceable and measurable on the coast of Sweden and Norway.

A change of a few degrees of temperature, a change of the relative height of the land, a change even in the polar distance of the masses of land, would materially affect many secondary phenomena. The atmosphere would be affected in regard to its moisture, translucency, rate of diminishing temperature, prevalent winds, and quantity of rain. Its power of sustaining particular organic structures both on the land and in the sea would be altered; and thus we see in the variable nature of the relations which unite the land and the sea, elements of continual change in the mechanical, chemical, and vital phenomena of the globe.

The ocean is continually receiving the spoils of the land, by means of the rivers and the action of the waves on the sea-coast; and from that cause, theoretically, would be constantly decreasing in depth, and as the quantity of water is always the same, its superficial extent would increase and its level consequently rise. There are, however, counteracting causes to check this tendency; the secular elevation, or gradual elevation during the course of ages, over extensive tracts in many parts of the world, is one of the most important of these. Volcanos, coral-islands, as well as the coral structures called barrier-reefs, show that great changes of level are constantly taking place in the bed of the ocean itself. In addition to these, it has been conclusively evinced by Mr. Darwin, that symmetrical bands in which the bed of the sea is subsiding below and being elevated above its level at a given time, extend alternately over an area (in the Pacific and South Atlantic oceans) equal to half that of the entire globe. From all these facts it may be concluded that the balance is always maintained between the land and the sea, although the distribution of each, respectively, may vary in the lapse of time. But independently of all these counteractions, so immense is the proportion which the magnitude of our planet bears to the power of the agencies which are at work upon its surface, that, as has been shown by Mr. Alfred Tylor, in a communication to the Geological Society, the action of the sea on the shores, and of the rivers upon the land,—if the matter they all wear from the land, and carry down in the form of sand and mud, together with that, probably still greater in quantity, which they carry down in chemical solution, to be decomposed in the sea, and in part precipitated on its bed,—were uniformly distributed over the entire bed of the ocean, the level of the water would not be raised more than three inches in ten thousand years, which is an amount absolutely insignificant, and would not be measurable for many times that period, nor otherwise sensible to man for many more.

What is the actual mean level of the sea? By the researches of Captain Denham at Liverpool, by the careful measurements taken by Mr. Bunt in the Bristol Channel, under the direction of Professor Whewell, and by some experiments of Sir H. de la Beche on the coasts of Pembrokeshire, it appears that the mean of high and low water is nearly at the same point, whether spring or neap tides be measured. This mean or half-tide level, which is often nearly coincident with the middle point of time between high and low water, can be ascertained by a few observations at any age of the moon in quiet weather, and should always be employed as the datum or zero line in recording elevations of mountains, heights of canals, summits, railway stations, &c. Above all it should be taken for the term of comparison whenever it is wished to determine the relative elevation of different parts of the open sea, though there may be cases when landlocked waters and tide rivers may require the use of another line of reference. The horizontal line which bounds the land and sea, the outline of the coast, is variable; it is annually displaced by the wasting of some tracts and the augmentation of others. Since the Roman sway in Britain, a large portion of the rich marsh-lands of Norfolk, Cambridge, Huntingdon, &c., have been recovered from the retiring sea; but in the same period the east coast of Yorkshire has lost many square miles of territory, and is still losing at a fearful rate. (Sir C. Lyell has collected abundant examples in his 'Principles of Geology.') This unequal action depends partly on the *slope* with which the land and sea meet; partly on the nature of the materials comprising the coast, partly on the *set* of the tides and currents.

The modern ocean is the theatre of many operations similar in kind to those by which the materials of dry land were formerly accumulated beneath ancient seas. The bed of the Adriatic was found by Donati to resemble the surfaces of sub-Apennine tertiary strata; the shallow soundings of the English Channel and German Ocean show, in the distribution of shells and fish-teeth, analogies with several of the secondary rocks; while in the coral reefs of warm latitudes, on sandy or pebbly shores generally, and at the mouths of great rivers, we see the production of limestone, sandstone, and clay deposits, very similar to those which abound in the stratified masses of land. Whoever will compare with attention the ripple or current mark on the sea-shore with the corresponding undulations on slates and sandstones of every geological age, will be convinced of the identity of the causes of these impressions; and when he beholds such surfaces in rocks covered by other deposits thousands of feet thick, will not hesitate to admit in such cases that great depressions happened along the margin of the ancient sea during the formation of these strata, followed by still greater elevations at a later period.

The distribution of life in the modern ocean is one of the circumstances most important to know. Until very recently it has been supposed that below some moderate depth (moderate at least as compared with the thicknesses of the strata) life ceases in the ocean from deficient light and air, and augmented pressure.

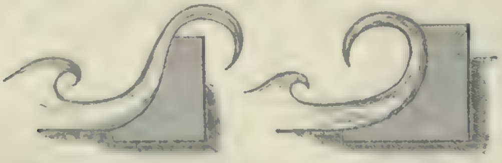
Within these few years, however, reason has been seen to modify these conclusions; and in the course of the past year (1860) the researches of Dr. G. C. Wallich, on the bed of the North Atlantic, have shown that animal life, in various forms of foraminifera and radiata, if not of higher groups, exists at vast depths. It ought, indeed, to have been seen long ago, that the uniform distribution of pressure effected by the water, would necessarily preclude the destruction which it was reasonable to infer that the partial accumulation of pressure would have caused.

The proportion which exists between the sea and land has contributed to maintain the productive powers of the earth. If that proportion were materially changed, its productive powers would be changed also. The sea, by means of the vapours continually rising from its surface, supplies the atmosphere with sufficient moisture for the support of organic life. Countries which do not partake of the benefits derived from this source, and which are not refreshed by rain or dew, are uninhabitable and destitute of all kinds of vegetation. Those parts of the earth which are farthest from the sea are much less fertile and populous than those which, owing to their greater vicinity to it, receive a larger supply of moisture from this great source. The sea contributes also considerably to the advancement of civilisation. At the first view it seems to constitute an insuperable obstacle to the communication between nations who inhabit countries widely apart from one another; but the ingenuity of men has converted the ocean into the most frequented high road on the globe. The easy communication which is thus established between nations at great distances from one another, has perhaps more than any other circumstance contributed to improve the condition of the human race. It is at least certain, that all those nations which have acquired any considerable degree of civilisation inhabit countries either contiguous to the sea or at no great distance from it.

On the subjects of this article, four works may be particularised, which, of course among many others, may be consulted with advantage: Sir John F. W. Herschel's 'Physical Geography;' Admiral Smyth's 'Mediterranean;' Sir John Richardson's 'Polar Regions;' and 'The Physical Geography of the Sea, and its Meteorology,' by Captain Maury, the American hydrographer. The last is an immense repository of facts, relating chiefly, however, to the Atlantic and its marine dependencies; and many views entertained by the author are not wholly accepted by British hydrographers and meteorologists.

SEA DEFENCES. When the tidal action, or littoral currents attack a sea-shore, it becomes necessary to protect the latter from the gradual abrasion thus produced. The mode in which the defences thus required are constructed, must depend not only on the peculiar form of destructive action to be guarded against, but also on the nature of the materials at hand; the various conditions to be observed may, therefore, be the most conveniently noticed in the course of the description of some of the most important works of the kind actually executed.

On rocky shores of the granitic and crystalline formations, the sea acts principally by its direct impact, or by the tidal currents, although, no doubt, the effect of the constant humidity, and of the splashing of the waves, must produce a destructive action on the constituent parts of the rocks. In these cases, and especially when deep water comes close in-shore, the most economical, and in all cases the most efficient sea defence consists of a solid masonry wall, built of the largest and hardest stones which can be obtained, and finished with a curvilinear batter of about 1 in 40 from the sea. Colonel Emy, and the French, Spanish, and German engineers sometimes make the upper parts of their curvilinear defence walls continue beyond the axis of the curve, so that at the top the curve again comes towards the sea; and they adopt this construction because they believe that, in consequence of the projection of the top, the crown of the wave striking and running up the face of the wall would be thrown outwards, instead of breaking over the wall. It is to be suspected, however, that the repercussion produced by the wave falling upon the toe of the wall is even more injurious than the effect of the water falling at the back or inside; and the best hydraulic engineers at the present day are in the habit of erecting their sea-walls with continuous batters in the same direction, and of protecting their in-shore faces by good paving on the top of the backing, and by good drainage. It would be impossible to attach too much importance to the necessity for providing against the effect of any sudden interference with the translation of a deep sea wave, especially when it has been driven for a short distance over an inclined fore shore, and has been exposed to the action of winds or currents able to increase the velocity of its motion. In some cases, the velocity has even been observed to attain as much as 70 feet per second; and from observations made at Cherbourg and Algiers, it would seem that the power of waves to communicate horizontal motion sometimes attains as much as 291 lbs. per foot superficial. The spray has at times been dashed over the Bell Rock, a height of 117 feet; and Lord Adair states, that he has measured on the coast of Ireland, rolling breakers of 150 feet in height. The quantity of water a wave of this description might carry over the crown of a wall would be enormous; and though there may be few positions wherein they occur, even smaller waves are capable of producing effects of a very serious nature, if the water they furnish were not prevented from washing away the backing of the structure on which they might break. On the shores actually exposed to the shock of such waves as those described by Lord Adair, it would be almost impossible for human skill to contend with the forces of nature; but fortunately, these waves are only to be met with on what are known as iron-bound coasts, where the character of the rocks is such as to enable them to resist the action of the sea.



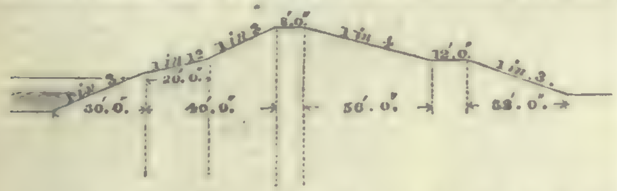
It may be gathered from the preceding remarks, that if it be thus necessary to guard against the tendency of breaking waves to produce lateral displacement, and to remove the backing of a defence wall, it must be equally important to guard against the tendency to undermine the footings on the seaward face produced by the receding wave, or the *undertow* as it is technically called. This object is usually effected in the more moveable strata, by constructing an apron, or in fact, a species of flat wall, presenting the same inclination as the natural line of the fore shore; and built with every precaution to ensure the stability of its face, by the introduction of longitudinal and of transverse ties, and by protecting the edges by continuous piling. At the Plymouth breakwater the sea slope was paved with large blocks of marble, or of granite, dovetailed and cramped together at an enormous cost; at Cherbourg, the sea slope was protected by huge blocks of rubble masonry set in Portland cement; and on the Dutch coast, where the angle of inclination of the shore is extremely flat, the apron walls of sea defences are often made of brickwork set with trass mortar in wooden frames. The choice of the system to be adopted in any particular case must depend on the maximum violence of the waves there observed; but it may be worth while here to mention that in exposed situations on the shores of the ocean, blocks of nearly 500 cubic feet, of a material possessing a specific gravity of 2·2, are susceptible of being displaced by the force of the waves.

These remarks with respect to defence-walls on the shores composed of resisting rocks apply equally, or rather *à fortiori*, to the defences required for formations of a softer nature. The action of the sea upon them is, however, of a rather more complicated nature than that which takes place on granitic, or crystalline shores; for it will in many cases be found that at the feet of limestone, or clay cliffs, there are large deposits of shingle composed of the detritus of harder rocks, carried forward by the force of the currents, and of the tides, according to peculiar laws. If this shingle should only advance slowly it may tend to protect the surface of the shore, by forming as it were a matlass on which the waves might break without affecting the subjacent rocks; but if, on the other hand, the shingle should have any tendency to lateral displacement, it will materially assist the abrading action of the littoral currents by the friction it exercises at the base of the cliffs. The outlines of a limestone, or of a clay, shore often bear traces of this action; and they exhibit cliffs which are nearly vertical in their upper portions, but hollowed out about the zone of tidal action; at their feet there is usually a shingly beach, in which the stones have been abandoned by the receding waves according to the specific gravities of the stones themselves, or, in other words, the largest pebbles are always at the top of the beach. The defence of shores of this description may either be effected by walls with aprons, as before-mentioned, or by the construction of stonework, or of timber, groynes, placed at right angles to the advance of the shingle, in order to fix the latter. Groynes are in fact dwarf-walls, projecting more or less above the face of the beach, and continued to about the line of low water; and they act by retaining the advancing shingle in the re-entrant angle, until it has accumulated to such an extent as to be carried round the point, or over the top of the groyne. In great storms the groynes are often laid bare, and there is danger of their being then undermined; and, indeed, the actions to which they are exposed are so violent, that it may fairly be laid down as a rule that it is preferable to form them of cheap, temporary materials, than to form them in a permanent manner.

The consolidation of shores of soft alluvial formations may be effected in various manners, according to their outlines under the action of the currents. If the natural inclination should happen to form a very small angle with the horizon from the line of the low water, it would generally be desirable to crown the top of the slope by a vertical wall, of either masonry or of timber. In Holland the dykes are executed of earth work, sometimes with rather an abrupt talus towards the sea, which talus is protected by stone pitching; at others the slope is made with a much flatter angle, and two or three parallel rows of piles, standing up above the face of the slope, are inserted for the purpose of breaking the force of the waves; and at others, the face of the earthwork is protected by a species of wall composed of bundles of reeds, fascines, &c. The hearts of these embankments are formed with reeds and fascines, and especial care is taken to attach them firmly to the subsoil, as well as to secure an efficient system of back drainage. Many instances occur in which the banks of the more protected polders of Holland and Flanders are constructed in the same manner as coffer-dams, that is to say, by means of puddle banks rammed in between sheeting enclosures; and near Havre, in the bay of the Seine, the fore-shore is defended by a regular timber stockade formed of whole timber piles, whales and back ties, and of horizontal planking spiked to the outer faces of the piles; earthwork is carefully rammed at the back of these planks.

It is necessary to guard against the destructive chemical action of the sea-water upon the materials employed for any of these systems of shore defences; and when the soft limestones, or wood, are employed, to take seriously into account the ravages which may be committed by the various descriptions of boring conchiferæ, and worms. The pholas, solen, and lithodomus attack the calcareous stones; the teredo navalis and the lymexylon attack wood, in the temperate latitudes of Europe; in tropical climates there are other species of animals of even a more destructive nature still, which feed upon, or burrow in, both those classes of materials.

It may be as well to add, that in the cases wherein the Dutch engineers content themselves with sand dykes, faced with reeds, the minimum dimensions they employ are about as indicated in the sketch;



but in very many instances they make the sea-slope with an inclination of even 1 in 20, when the natural profile of the foreshore presents a very flat incline. With the very light materials dealt with in these cases it is indeed preferable to conduct the waves up a long easy slope on which they can exhaust their power, than to attempt to oppose an abrupt resistance to their shock. When stiff clay is the material used for the banks, and no protection is given, the slope is made equal to 1 in 10; when light sand is used, the slope is made 1 in 20, whatever may be the profile of the foreshore. At the mouth of the Thames and Medway the marshes are defended by slopes of 1 in 4, protected by a concrete bed covered by stone pitching, laid between rows of stakes driven firmly into the banks, and between rows of piles at the top and bottom. (See Minard, 'Ouvrages Hydrauliques des Ports de Mer, &c.')

SEA LIGHTS. [Trinity House.]

SEA SALT. [Sodium. *Chloride of Sodium.*]

SEA WATER. [Sodium.]

SEAL, an intaglio or relief impression on wax, clay, paper, or other substance made from a die or *matrix* of metal or other material, by which the impression is produced, derived from the French *sceau*, *scelle*, or *saiel*, first used in the 11th century; the Latin *sigillum*. Seals, called *khatem*, were in use at the earliest period in Egypt, the matrix generally of square shape revolving in a large ring, or attached to a chain; those of kings and high dignitaries of gold, silver, or precious stones, while the inferior people used scarabæi, *kheperu* of porcelain, or vitrified soapstone with the subject engraved in intaglio, set in rings as signets. Impressions or seals from these were made in fine Nile mud or clay, and attached by slips of papyri, linen or cord, to documents [Papyrus], while at a later period coloured wax and even lead were employed. [Mummy.] The engravings were deities, royal and other names, emblems and mottoes. Impressions of seals with the names of Sheshank, Nafaarut, Amasis, and other monarchs, exist in the British Museum. Seals were extensively used by the Egyptians: tombs were sealed with mortar, letters and other documents being rolled in a cylindrical form and sealed outside, and the sacred victims, bread, and other objects, were also sealed. The ancient Hebrews appear to have worn their signet-rings or *khatam* as rings or bracelets (Gen. xxxviii. 18); they were made of engraved onyx (Exod. xxxix. 6), and documents were sealed with them. Ahab with his own hand; Ahasuerus by his chancellor Haman, and Darius himself, impressed the seals of their decrees. When Alexander the Great conquered Persia he used the seal of Darius for his rescripts in that country.

The signets of the Assyrians consist of cones of chalcedony and other stones pierced and engraved, which were set in rings or suspended to chains or cords: the principal device is a rampant lion pierced by a king, deities and other devices; they also used cylinders of green felspar and onyx, with kings, animals, and other objects, and inscriptions containing the names and titles of kings, those of Sennacherib being found at Kouyunjik (Layard, 'Nineveh and Babylon,' p. 154). Impressions from similar signets in fine clay were discovered in the ruins of Kouyunjik, and those of witnesses or contracting parties are found on clay documents. The use of cylinders, for this purpose, of hematite, steatite, chalcedony, and onyx was prevalent amongst the Babylonians, such being engraved with deities, zodiacal signs, and inscriptions, and continued under the Persians, who used by preference red cornelian, that of Darius or his viceroy having been found in Egypt. The Phenicians appear to have employed scarabæi of cornelian or sardonyx for the same purpose, and the Etruscan signets were scarabæi of the same or onyx, with devices of native deities, or the principal heroic and mythic personages of Greece, with Etruscan legends.

At the earliest epoch the Greeks used impressions of worm-eaten pieces of wood. The use of signets and seals among the Greeks appears to be as old as the 6th century B.C., the earliest example being the celebrated emerald ring engraved by Theodorus for Polycrates, tyrant of Samos. Such signets were called *sphragides*, *semata*, *semcia*, or *semanteres*, and were worn on the fourth finger of the left hand. Those of metal only were called *apsephoi*, the stone itself being *psephos*, and the chaton *sphendone*, *ecmageion*, *aposphragisma*, *ectyposna*. The impression of the seal was made on a fine clay, the *ge semantris* or sealing earth, not wax. Seals were placed on doors, and on things in the house to prevent the pilfering of slaves. The seal itself was protected by a shell or scale.

The use of signets amongst the Romans appears to have been introduced by the Etruscans, whose *gemmati annuli*, or rings with stones, were subsequently used by the Romans as old as Tarquin the elder. Senators sent as ambassadors had a gold official signet given them by the State, but used an iron ring in private: gold rings or signets were limited to the senators and knights, and the *jus annuli aurei*, or rights of the gold ring, had a certain legal status under the Empire. But their use was extended by Tiberius to freedmen, by Severus Alexander and Aurelian to the troops, and under Justinian it had entirely disappeared. The signet of the Emperor was a state seal, generally engraved with his own portrait or favourite device. The chaton, or place which held the stone, was called *pala*. The various gems were engraved by excellent artists, who sometimes placed their names, or the name or initials of the possessor, on the stone; but glass seals, called by the Greeks *sphragides hyalinai*, and *vitreæ gemmæ* by the Romans, were used by the poorer classes. These came first into use about 416 B.C. The impressions were made in Lemnian and sealing clay, *cretula*, *sigillaris creta*, stucco *maltha*, or still more frequently wax. The Romans sealed bags of money, granaries, doors of female apartments, and other objects, but principally writings or letters; the papyrus or tablet was tied up with a cord and the seal, *signum*, placed on it; wills particularly required seals, and under Nero the law ordered them to be pierced at the margin with a cord, which thrice passed round them, and the seal was then applied, and the prætor required the seals of the seven witnesses to validate a will. The devices of the seals of the emperors appear to have varied, and no particular symbol was used for the state seal. Julius Cæsar used Venus, Augustus a sphinx, which he changed for the head of Alexander the Great, which continued till Nero; the following emperors used various symbols. Private individuals used indifferently all sorts of devices During the Empire leaden seals were used for private purposes, and after the age of Constantine, flat circular metallic seals called *bullæ*, made of gold, silver, and lead, attached by silken or woollen bands to the documents, came into use.

The Byzantine commence with Valentinian and Valens, A.D. 364, and have on one side the figure of the Emperor, on the other that of Christ or the Virgin; dignitaries and private persons of the epoch also employed leaden seals, with Christ or the Virgin, or only their own names and titles. The devices of the seals of the Christians at this epoch were fishes, fishermen, lambs, and vines. After the fall of the Western Empire the use of the leaden *bullæ* was assumed by the Popes, the oldest known being that of Deus dedit, A.D. 615-667, with a male figure standing between a lion and a lamb and A.Ω. Small seals were inscribed only with the names or monograms till Honorius II., 1124-30; but at the 12th century, the bullæ became larger, and the name of the pope appeared in full, with the heads of St. Peter and St. Paul, and a cross between them; the ordinal after the papal name dates from the 11th century. Besides these the Popes used the so-called seal of the Fisherman, or privy seal, on which was St. Peter fishing: this was impressed on red wax *en placard*. The use of the bullæ in Western Europe continued till the 16th century, the Emperors of Germany, princes of Calabria, the doges of Venice, dukes of Lorraine, and counts of Toulouse, continuing to use them. In the 13th century no priest was allowed to travel without a permission sealed with a leaden seal. The use of golden seals commenced about the 10th century, having been first used by the Byzantine Emperors and Charlemagne, Venetians and others, and occasionally for important documents as late as the 16th century, Henry VIII. and Francis I. having appended gold seals to their treaty at the Field of the Cloth of Gold. Silver seals were sometimes used by the Byzantine Emperors, the princes of Capua, and other Italian potentates. But all these were gradually superseded by wax seals. On the fall of the Roman Empire the art of seal engraving was lost in the West, but lingered at Constantinople. The early kings of France from Carloman, A.D. 769, to Louis VIII., 1176, used antique gems. Sealing *en placard* continued in France from Clovis I., A.D. 481, to Louis le Gros, 1108, in whose reign seals were first appended, and in Germany till the close of the 12th century.

The seals of the Merovingians represent busts with long hair, the Carlovingians bearded profiles, but appear to be impressions of ancient gems. The title of Dei gratia commences with Charlemagne; Hugh Capet, 987, is first seen with a sceptre. Robert has an oval pointed seal with a half-length figure. Henry I., 1031, was the first who used the seal of Majesty as it is called, representing the king seated on the chair of

Dagobert. Louis VI., 1108, is the only one with an equestrian figure on the reverse. Small counterseals on the reverse commence with Philip II., 1185. Louis IX., 1252, first appears with a crown fleury. John II., 1350, has two eagles' heads on his chair. Louis XII., 1500, a double gryphon. The king seated on the throne continued to be the type, with the exception of the great seal of Louis Philippe, which has on one side his head in profile, and on the other his arms or the two tables of the charter and law. The early seals of the German empire are like the French. Henry II. introduced the seated figure, which, after Frederick I., 1493, was abolished. Denmark used bronze seals; the Swedish seals resemble the German; those of Spain date from the 12th century; the doges of Venice, 1306, used gold bullæ.

The seal was placed after the name of the chancellor or his deputy in white wax; an incision in form of a cross, or with saltire edges turned back, having been made in the parchment and passed through, so as to form a cake or mass on both sides. This mode of sealing *en placard* being easily forged, the counter-seal was introduced by the princes of Lombardy, A.D. 901. The custom of appending seals was not introduced earlier than the 12th century; tails commenced in the 13th century, leather, hempen string, silk, parchment, were used for the purpose, and the seals were placed at the bottom, top, sides, or even all round the document. As many as 350 seals were appended to one document presented to the Council of Constance. Owing to the injuries to which seals were liable, it was not unusual from the 14th to the 16th centuries to protect them by a little frame work or torse of rush twisted round the seal; in the 14th century a wrapper of paper, neat bands of the same, beech, bay, and oak leaves, were placed over seals, and in France in the 15th century they were protected by tin boxes.

The French regal seals differ from the English and German by the use of the counterseal, which is not more than an inch in diameter; while the great seal of England retained an impression of the same magnitude on both sides. In France, during the 1st race, the seal was held by the *referendarius*, under the 2nd, or Merovingian, by the *archichancelier; aprocrisaire, archinotaire, archichapelain*, under the 3rd, or Capets, by the chancellor, who originally wore the seal round his neck, but when the seal became of large size, it was deposited in a box, and the chancellor always carried the keys about him in a purse, and the box was carried in certain ceremonies on a caparisoned horse. In this box were three others: 1st, for the great seal and counter-seal; the 2nd, that of Dauphigny; the 3rd, that of the order of St. Louis, besides which, the king had his private seal. Yellow wax was used for the impressions, except for ordinances, edicts, and letters entitled "à Tous presents et à venir," which were sealed with green wax, and the same colour was used for those of Dauphigny; other documents of which were sealed in red. In 1789, the office of chancery disappeared, but a new one was re-established in 1808, and superseded by a commission in 1811, and in 1830 incorporated with the office of minister of justice.

The earliest seals of the Anglo-Saxon monarchs, Offa, Ethelwolf, and Edgar, are *en placard;* of Coenwulf, 755, there is a leaden bulla; of Edward the Confessor, two wax seals pendent. Coke mentions seals of Edwy, A.D. 956, of Offa, A.D. 755-94. The Normans introduced wax seals, at first of moderate size, having on the obverse the king in armour on a caparisoned horse galloping, and on the reverse, the king seated on a throne, a type maintained to the present day. The expense of engraving a new matrix being very considerable, the monarchs were content to use those of their predecessors. Edward II. added to that of Edward I., and Edward III. used the same with the addition of two fleur-de-lis. Edward III. altered his seal eight times for political purposes. Richard II. used his father's last matrix, merely inserting his own name. Henry IV. and V., the same, by the same process. Henry VI. a new matrix, like the French, with a counter-seal. Edward IV. a new gold seal, like that of Bretigny; Edward V. his father's, and Richard III. the same. Henry VII. a new matrix, like that of Edward IV., and Henry VIII. one in the style of Francis I. The matrix of the seal of Henry IV. was of gold, the chancellor used a silver matrix, which was of 10 lbs. weight, and cost 13*l.* 10*s.* for material alone. The great seals of Scotland commence with Duncan II., 1096, with equestrian and seated royal figures. Alexander I., 1107, introduced the counter-seal. There were also great seals for Ireland, commencing with Henry II., a leaden matrix of which is known. There are, besides, the privy seals, having the royal arms only.

Next in importance to the royal seals are those of the ecclesiastical bodies and dignitaries. At first the bishops only used a private or peculiar seal, but at the close of the 9th century each prelate began to use a particular form of seal, in which was impressed the name and titles, and image, at first half length, then standing or seated, clad in his pontifical dress, and holding a crozier in one hand while giving the benediction, or holding the gospels in the other. During the 11th and 12th centuries the bishops were presented either standing or seated, but in the 13th and 14th the seated attitude specially designated the episcopal office. Sometimes the figures of the saints were substituted for those of the bishops. During the 13th century mottoes were introduced. In the 14th century the designs became more rich and varied, and in Germany the bishops and other religious functionaries placed their escutcheon on their seals beside their figure. In the 15th century the escutcheon, used at first only for the counterseal, became substituted for all other devices with few exceptions. Latterly the devices of the episcopal seals in France have been an imitation of those of the 13th century. The corporate seals of the abbeys, chapters, and other ecclesiastical bodies often have a representation of the religious edifices to which they belonged, or figures of the patron saints. The abbots and priors and prioresses often impressed their own images; the numerous minor functionaries were restricted to a device, or the figure of the patron saint.

The corporate seals of the 12th century have the towers, castles, gates, or city walls, the use of armorial bearings, which superseded ultimately all other subjects, not being older than 1365. The mayors and other municipal functionaries used a device or the city arms. In England the cinque ports have ships of war. The devices of the seals for the passes or passports of labourers were prescribed by the statute 12 Richard II., 1388.

The use of seals, as a legal formality, was introduced into England by the Normans during the 11th and 12th centuries. All persons of the ranks of knights and above used a horseman armed at all points going to the fight or chase; females had their effigies; but rude forms, birds, eagles, hawks, lions, dragons, crescents, and stars, are the common devices of the period. The legend surrounding the device, generally in Latin, contained the name and titles of the bearer. Secular persons used circular seals, ecclesiastics and women the pointed oval; counter-seals, *secreta*, do not occur earlier than 1170: the wax used was white bees'-wax, sometimes painted red, but green wax became common at the close of the 12th century; during the 13th and 14th centuries armorial bearings were introduced by the knights and others entitled to wear them, while the middle casses adopted arbitrary devices—fleur-de-lis, agnus dei, &c., grotesques, and emblems of their craft or calling. From the reign of Henry III. the style and art much improved; the shape of almost all the seals of this period is oval, the wax generally green, and the counterseal from the year 1200 in common use. After the year 1400, personal seals, not of an armorial character, decline in size and importance; and merchants' marks composed of monograms, introduced by the Flemings, are common devices of the 15th and 16th centuries. From the 12th to the 15th century antique gems set in silver were often used.

Personal seals have either the representation of the person to whom they belong, armorial bearings or arbitrary devices; only the nobility used personal effigies, as armed, on horseback, or holding their shields; ladies stand holding a bird or fleur-de-lis. Equestrian seals are circular, the others pointed. Armorial bearings begin in the 12th and continue till the 13th century; at the end of the 15th the middle class assumed coats of arms. Plain arms on pointed shields are the oldest; at the 15th century the shields are surrounded with drapery. They are generally orbicular, elliptic, or in form of a shield, and the matrices were flat, with a dorsal ridge and little ring; at the middle of the 14th, helms with feathers, crests, and support appear, and Gothic letters, which become common in the 15th century. Seals with grotesque devices and mottoes, assumed at pleasure, were in general use during the 14th and 15th centuries: love seals had two heads facing; and a favourite device was a squirrel. But after the 15th, and in the beginning of the 16th, a great change took place, the wax was covered with white paper and impressed, and at a later period wafers placed between paper were introduced, while sealing-wax was invented by Rousseau in the 17th century, and the seal, originally the substitute for the signature, at last degenerated into a legal formality and fiction.

The matrices of the early mediæval wax seals were made of lead for the middle and poorer classes, silver appears to have been used by the nobility; and in the 13th century a mixed metal resembling brass, long confined to Cologne, was used for the matrices; jet was used occasionally, and the matrices worn as amulets. The matrices are generally flat disks, about ½ inch thick, sometimes with a dorsal ridge and a ring or loop for suspension. The double seals have projecting rings at the sides, with pins for securing them when in the press. The shape varied at different epochs: under the Merovingians they were orbicular; under the Carlovingians, small oval. In the 14th and 15th century the sizes increased; but the ordinary forms are pointed vesica, oval, and angular; although trefoil, horseshoe, lozenge, square, octagonal, and other varieties occur. The matrices were sometimes forged, dies of Pius II. for making false bullæ having been found in London, and a false leaden matrix of Henry II. for Ireland still existing. The colour of the wax differed according to the period: white was employed by the French kings of the first three races, the emperors and prelates of Germany, till the 13th century; the kings of England from the time of Charles I., and some orders of knighthood. In France, Louis VII., A.D. 1137, first used red wax; William II., in England; and Frederick Barbarossa, in Germany; and monastic orders and territorial barons for judgments, quittances, and other charters during the 14th and 15th centuries. Philip Augustus, A.D. 1180, first employed green wax, which was also used by the nobility and ladies. Black was employed by the Teutonic order in the 13th century. The form of the letters of the inscriptions changed from time to time; Roman capitals were in use till the 12th century, when Gothic letters commenced with the form SI, SIG, or SIGILLVM; and in the 14th century the legend was preceded by a cross +, and later by a rosette or star. Latin was the language usually employed. The name of the seal was sometimes on the legend, as *sigillum com-*

mune, common seal; *sigillum secretum*, privy seal; *contrasigillum*, counterseal. The early French seals have invocations, as *Christe protege Pippinum Regem*, "God save king Pepin."

In England, the seals of conveying parties are now essential to all legal instruments whereby real estate is conveyed. The law recognises three royal seals, the great seal in custody of the chancellor, attached to all letters patent, grants of inheritance, or chattels real, offices in fee and writs at common law, the privy seal kept by the Lord Keeper, valid for the issue of treasure, disposition of chattels, contracting or discharging a debt; the signet, or privy signet in custody of the principal secretaries of state, valid as authenticating the sign manual, and for the writ *ne exeat regno*. The counter signature of a principal secretary of state is required by a statute for the use of all the seals. (Comyn, 'Digest,' Patent; Coke upon Littleton, by Hargrave and Thomas, ii. 233.)

Among oriental nations seals have been employed as a stamp. The Chinese great seal called *se* dates from the Tsin dynasty, B.C. 248, under whom they were square; under the Hân dynasty they became circular. Other seals *yin* are generally square and made of gold, silver, copper, crystal, porcelain, steatite, wood, and other substances, of tall rectangular shape, surmounted by figures of lions, apes, dragons, and other animals. They generally have mottoes or sentences from Chinese classical authors, and impressions in various coloured inks are stamped in important places on commercial and public documents, books, and papers. The Arabs and Indians, from the earliest times, have used metal seals and gems to impress by means of black ink impressions on their books and other documents; only wax has, however, been used in modern times.

The study of seals is one of the most important in archæology; after the fall of the Roman Empire they replace the loss of gems and show the state of the glyphic art; of architectural progress; of Christian symbolism till the present day; at the same time throwing great light on the history of states and families, their heraldic devices and genealogy.

Mabillon, *De re diplomaticâ*, fo. Par. 1681; the Benedictins' *Traité de diplomatique*, 4to Par., 1759; De Wailly, *Elements de Palæographie*, 4to, Paris, 1858, vol. ii.; *Travaux de la Société Sphragistique de Paris*, 1852; *Proceedings of the Archæological Institute*, London, 1836-61.

SEALING-WAX. The best red sealing-wax is composed of shell-lac, Venice turpentine, and cinnabar. The shell-lac by itself is rather too brittle, and the turpentine is added to remedy that defect. The proportions are about four parts of lac, one part of turpentine, and three parts of cinnabar, by weight. When the lac and turpentine are melted, the cinnabar is added in powder, and the whole is well mixed by stirring it about. The round sticks of sealing-wax are made by hand on a smooth slab of marble or plate of metal, which is kept at a moderate temperature by a brazier placed beneath it. The liquid sealing-wax having been partially cooled, a quantity sufficient to make about six sticks is rolled out on the slab or plate into one long stick; which, when of proper diameter, is cut into lengths, and transferred to another workman, by whom the sticks are rolled on a cold slab beneath a smooth piece of wood or metal. The sticks are now polished, which is done by holding them successively between two contiguous charcoal fires till the surface is fused, which produces the polish. One end is then softened by being brought near the flame of a lamp, in order to receive the impression of the maker's name. This manipulating process is only applied to the round sticks; those which are oval and ornamented are formed by pouring the liquid sealing-wax into a mould; when partly cooled, the sticks are removed to another mould made of steel, out of which they are taken polished and fit for use.

For the best black sealing-wax, the finest ivory-black is substituted for the cinnabar. For sealing-wax of inferior quality, not only the darker-coloured shell-lac is used, but other resins of less value, common turpentines, and mixtures of cinnabar and red lead, or sometimes red lead alone; and lamp-black is used instead of ivory-black. Other colours are given to sealing-wax by mixing with it, for the most part, different metallic oxides.

The softer wax, which was formerly in general use for sealing letters and legal documents, and which is still occasionally used for the latter purpose, consists of about four parts of bees'-wax, one part of Venice turpentine, and as much cinnabar or other colouring material as is required to give it the tint which is preferred.

SEAMEN. [SHIPS.]

SEARCH, RIGHT OF. The general principles upon which that part of the law of nations is constructed which respects the usages to be observed towards neutral powers in time of war by the belligerent powers, have been explained under the head of BLOCKADE. Here it is only necessary further to remark that manifestly no other right can be exercised by the belligerent over the ships of the neutral without the right of visitation and search. The existence of that right, accordingly, to use Lord Stowell's language in the well-known case of the Maria (1 Robinson, 340), is acknowledged beyond all controversy as attaching to the lawfully commissioned cruisers of the belligerent nations, whose rights cannot legally be varied by the interposition, in any manner of mere force, of the authority of the sovereign of the neutral country: a right that is as reasonable as it is necessary, for, as his lordship says, "Till they are visited and searched, it does not appear what the ships, or the cargoes, or the destinations are; and it is for the purpose of ascertaining these points that the necessity of this right of visitation and search exists."

In the exercise of the right of search upon a neutral vessel, which must be conducted with as much regard to the rights and safety of the vessel detained as is consistent with a thorough examination of her character and voyage (the Anna Maria, 2 Wharton's (Amer.) Rep. 332), the first and principal object of inquiry is generally the ship's papers. These are, the passport from the neutral state to the captain or master; the sea letter, or sea brief, specifying the nature and quantity of the cargo; the proofs of property; the muster-roll of the crew, containing the name, age, rank or quality, place of residence, and place of birth of each of the ship's company; the charter party; the bill of lading; the invoices; the log-book; and the bill of health. (Abbott, 'On Shipping,' 9th edit., 288.) Upon the subject of the ship's documents, it should be observed, that if she is not properly documented, or if there has been a spoliation of papers, and other signs of bad faith, these are grounds of unfavourable presumption, the effect of which is not to be avoided except by clear and satisfactory evidence to the contrary. (M'Lachlan, 'Law of Merchant Shipping,' p. 481.)

The penalty for the violent contravention of the right of visitation and search, is the confiscation of the ship and cargo; and a rescue by the crew after the captors are in actual possession is considered as the same thing with a forcible prevention. In either case the resisting ship may be seized in the same manner as if it belonged to the enemy, and, being brought into port, will be condemned as prize.

Of course, any of the belligerent powers may agree with any of the neutral states that the right of search shall only be exercised in certain circumstances; and this is the first limitation that falls to be noticed. "Two sovereigns," Lord Stowell has said in the same judgment, "may unquestionably agree, if they think fit, as in some late instances they have agreed, by special covenant, that the presence of one of their armed ships along with their merchant-ships shall be mutually understood to imply that nothing is to be found in that convoy of merchants' ships inconsistent with amity or neutrality; and, if they consent to accept this pledge, no third party has a right to quarrel with it, any more than with any other pledge which they may agree mutually to accept. But surely no sovereign can legally compel the acceptance of such a security by mere force. The only security known to the Law of Nations upon this subject, independent of all special covenant, is the right of personal visitation and search, to be exercised by those who have the interest in making it." Lord Stowell here alludes to the pretensions of the northern powers in their convention for the establishment of what was called an armed neutrality in 1800, one of the clauses of which was, "That the declaration of the officers who shall command the ship of war, or ships of war, of the king or emperor, which shall be convoying one or more merchant-ships, that the convoy has no contraband goods on board shall be sufficient; and that no search of his ship, or the other ships of the convoy, shall be permitted." It is sometimes stated that this was also one of the principles of the previous convention of the same kind formed by the northern powers in 1780; and there may perhaps have been an understanding among the contracting parties to that effect; but we do not find it distinctly avowed in any of their published announcements. The position in question, namely, that the presence of a ship of war should protect from search the merchantmen under its convoy, never has been admitted by Great Britain.

But it is now universally admitted that the right of visitation and search cannot be exercised upon a ship of war, or public or national vessel, itself; and this is the second limitation of the right. It is strange that there should ever have been any doubt or dispute upon this point. A ship of war has always been looked upon as in a manner part of the national territory, and as such inviolable in any circumstances whatever; the act of entering it in search either of contraband goods or of deserters must be considered as an act of the same character with that of pursuing a smuggler or fugitive across the frontier of the state without permission of the sovereign authority, a thing the right of doing which has never been claimed. Accordingly, although it has been a common thing for nations to declare by express stipulation in their treaties with one another that the prize courts in each shall exercise a jurisdiction according to the recognised principles of public law in questions arising with regard to captures at sea, the language used has always implied that the captures are to be merchant or private vessels: of the concession by one power to another of the right of adjudicating upon its ships of war detained or brought into port not a trace is to be found in any such treaty. Yet an opposite doctrine has been both maintained in argument, and attempted to be carried into effect. In 1653, when after the disasters of the war with England that had broken out in the preceding year, the Dutch were reduced to such a state as to make them anxious for peace upon almost any terms, the English government demanded as one of the stipulations of the proposed treaty that all Dutch vessels, both of war and others, should submit to be visited, if thereto required. But, humbled as the Dutch were, they peremptorily refused to agree to any such stipulation; and the treaty was concluded in 1654 without it. From this time, for more than a century and a half, the principle of the immunity of ships of war from visitation and search was acquiesced in by the practice of our own and every other country, nor is it known to have been contested even in speculation. But at length, in the course of the controversy that arose respecting the rights of neutrals out of the Berlin and Milan decrees of the French emperor and our own orders in council, in 1806 and 1807 [Blockade], while some extreme partisans on the one side contended that even merchant ships were not liable to search when under the convoy of a man-of-war, others on the opposite side revived the old pretension of the English republican government of 1653, and maintained our right of visiting and searching the ships of war themselves of neutral states whenever we should think proper. The practical application of the principle that was now especially called for was the visitation of the ships of war of the United States of America, for the purpose of recovering seamen alleged to be subjects of this country and deserters from the British service. An actual enforcement of the new doctrine occurred in an attack made, on the 23rd of June, 1807, by the British ship of war, Leopard, upon the American frigate Chesapeake, lying off the Capes of Virginia. On the refusal of the American captain to permit his ship to be visited, the Leopard fired into the Chesapeake, which, being unprepared for action, immediately struck her flag. Four men were carried off, and the American ship was then left. The American minister in London was directed to demand satisfaction of the British government. Negociations were continued for a long time without any result; the affair of the Chesapeake soon became mixed and complicated with other incidents, giving rise to new claims and counterclaims; at last the American government took its stand on new ground, objecting to the search not only of ships of war but even of merchant vessels for deserters; it was not denied that the search of merchantmen was sanctioned by the law of nations, but the exercise of the right was denounced as necessarily irritating and fraught with danger, and it was urged that it should on that account be dispensed with and abolished. In the end war broke out between the two countries in the summer of 1812; but even that did not settle any of the questions that had arisen between them in connection with the right of search. The treaty of peace signed at Ghent on the 24th of December, 1814, contained no stipulation on that subject, which was now supposed to have lost its practical importance. This question was again incidentally raised between England and America in 1842. In the discussion which then took place between Lord Ashburton and Mr. Webster relative to the boundary line of the state of Maine, the American minister intimated that the rule hereafter to be insisted upon would be that every regularly documented American vessel would be evidence that the seamen on board were American, and would find their protection in the flag that was over them; and again in 1854, when, after the issuing of the declaration by the Queen of England (on the 28th March), it was supposed to be her Majesty's intention to relax the right of search, the Attorney-General stated in answer to a question in the House of Commons (30th March), "That it never was intended to give up, nor did the declaration give up, the right of searching neutral vessels. It was impossible to give up that right, and this country still maintains its right to search and seize vessels which carry enemy's despatches, or articles contraband of war." But whilst England thus reserved to itself this right, she waived its exercise during the war, and on the termination of hostilities, concurred with France, Austria, Russia, Prussia, Sardinia, and Turkey, in establishing the principle that "free ships make free goods."

The maritime declaration appended to the Treaty of Paris comprises among others the following points:—

1. The neutral flag covers enemy's goods, with the exception of contraband of war.

2. Neutral goods, except contraband of war, are not liable to capture under the enemy's flag.

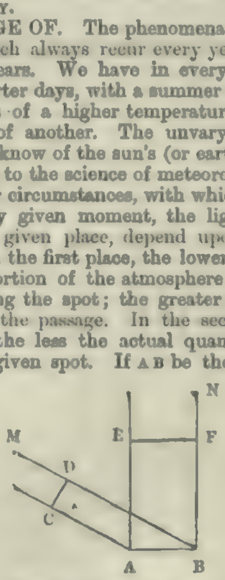
The United States, however, refused to concur in this declaration, unless it was further conceded that enemy's goods on board enemy's merchant ships should be allowed the same exemption as on board neutrals.

At present therefore it appears that the right of search, abolished so far as relates to *enemy's property* on board neutral ships by the Treaty of Paris, subsists as to the other points in respect of which it was formerly exercised, namely, the carriage of troops, hostile despatches, and contraband of war. (Arnold on 'Marine Insurance,' vol. i. p. 673.)

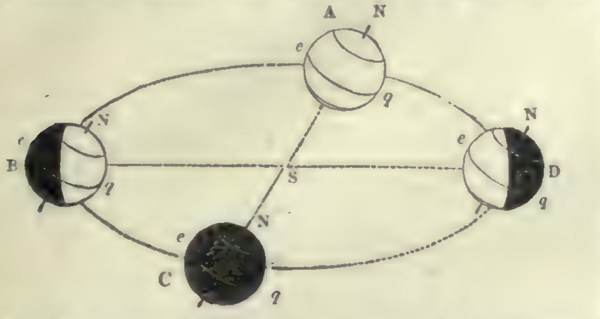
The right of visitation and search, however, is by no means necessarily confined to a time of war. Its exercise has always been admitted to be equally allowed by international law in time of peace, though it may not commonly have then been so frequently thought to be called for. The very question of the seizure by one country of its subjects serving in the mercantile navy of another, which was one of the main subjects of dispute between England and America before the breaking out of actual hostilities in 1812, may arise in a time of peace as well as in a time of war, though its importance no doubt is less in the former than in the latter. The chief questions connected with the right of search, the number of which is greatly reduced in a time of general peace, are those relating to the trading rights of neutrals; but even of these some remain. Of late years, however, the right of search has become principally important in reference to the trade in slaves, which has now been declared to be illegal by most of the great maritime states. The right of visitation and search, however its exercise may be regulated, seems to afford the only means of ascertaining whether or no a vessel has got slaves on board; but it is evident that any power opposed, for whatever reason, to the exercise of that right may, even while declaring the slave trade to be illegal, refuse to allow that illegality to be made an excuse for the visitation of suspected ships bearing its flag. It is only by express stipulation that the free exercise of the right can be established. England, which has all along been foremost in the attempt to suppress the slave trade, has never objected to the exercise of the right of search for this, or indeed for any other legitimate object; but other nations, jealous of our predominant maritime power, have, not perhaps very unnaturally, been extremely reluctant to concede it in this particular case. Probably the best illustration of these remarks is afforded by the Ashburton Treaty, and the attitude of American publicists with reference to it. By the 8th article of that treaty, each party was to maintain a separate squadron on the coast of Africa for five years, and the cruisers of the respective nations were to detain all vessels under American colours equipped for, and engaged in, the slave trade; that if proved to be American property they should be delivered to an American cruiser; and if proved to be Spanish, Portuguese, Brazilian, or English property, to an English cruiser. In the President's message (August 11, 1842), and in the discussions in the American House of Representatives, it was maintained, or attempted to be maintained, that the 8th article was a substitute for visitation and search; but Sir R. Peel emphatically declared that in acting upon the treaty England had not abandoned her claim to the right of visitation; and Lord Aberdeen's despatch, re affirming the British doctrines on this subject, recorded the determination of England not to depart from the principles she had constantly asserted. Upon this treaty, the debates in the British Houses of Parliament, the expressed opinion of the British Government, and the instructions to its cruisers, considerable discussions have been raised, and attempts have been made by American writers (among whom Mr. W. B. Laurence's recent treatise on 'Visitation and Search' deserves special notice) to show that the doctrines of England are unwarranted by law, dangerous to the welfare of other countries, and intended solely to promote the attainment of universal dominion under the guise of humanity; that the time has come when such doctrines must be energetically opposed, and that if they can be supported by an appeal to the language of treaties, then it is the duty of the States of the Union to insist upon the discontinuance of those treaties.

Some further remarks on this subject are briefly made under the article Slave, Slavery.

SEASONS, CHANGE OF. The phenomena of the seasons may be divided into those which always recur every year and those which are different in different years. We have in every year the same succession of longer and shorter days, with a summer and winter; while the summer of one year is of a higher temperature, and accompanied by finer days, than that of another. The unvarying phenomena can be explained by what we know of the sun's (or earth's) motion; the varying phenomena belong to the science of meteorology, and depend upon atmospheric and other circumstances, with which we have little or no acquaintance. At any given moment, the light and heat received from the sun, at any given place, depend upon the altitude of that body in two ways. In the first place, the lower the sun is, the greater the thickness of the portion of the atmosphere which its rays have to traverse before reaching the spot; the greater then is the light and heat which is lost in the passage. In the second place, the less the altitude of the sun, the less the actual quantity of light and heat which falls upon any given spot. If A B be the diameter of a circular portion of the earth's surface, and if the sun be seen in the direction B M, the light which falls on that circle is a cylinder of rays with the diameter C D; but if the sun be seen vertically, or in the direction B N, the cylinder of rays has E F for its diameter, besides which, the rays of the first cylinder are weaker than those of the second, as having passed through more of the atmosphere. Neglecting this latter consideration, the quantities of light and heat received when the sun is at two different altitudes are as the sines of those altitudes. Thus the sine of 30° being ½ and that of 90° being 1, the quantity of light which falls on a given spot when the sun is vertical is double of that which falls when its altitude is 30°.



The earth's axis preserves its direction throughout the whole of the yearly motion. The consequence is, that places which are distant from the equator have very unequal days at different times of the year. [Sun.] The accompanying figure, which is generally given in connection with this subject, represents the earth in its four principal positions; the sun being at S, and N being the north pole of the earth. A is at the vernal equinox, the intersection of the equator and ecliptic passes through the sun, and days and nights are equal all over the world. B is at the summer solstice, where the sun is most above the equator on the northern side; the diurnal circles north of the equator have more day than night, and have their longest days: and *vice versâ*. C is the autumnal equinox, the phenomena of A being repeated. D is at the winter solstice, where the sun is farthest from the equator on the southern side; the phenomena of B are now reversed, the days being shortest on the north side of the equator. This figure very well explains the variation of days and the main reason for the phenomena of seasons in the extra-tropical parts of the earth. It is evident that, speaking of the northern hemisphere, the sun, being above the equator, gives not only longer days, but greater altitudes; more powerful light and heat, and more of it in duration.



The average temperature being nearly the same in different years, the northern side of the earth must be receiving more than it parts with during a portion of the year, and parting with more than it receives during the remainder. The summer half of its year is that half during which it gains on the whole, more than it parts with; the surplus being that which is lost during the winter half. The day in which most heat is received is the longest day; but it is notorious that the hottest weather is generally some time after the longest day. This is easily explained, as follows:- The time of the greatest heat is not that at which most heat is received, but that at which the quantity of heat is the greatest, namely, just before the daily receipts of heat begin to fall short of the daily expenditures. So long as the receipt exceeds the expenditure, heat is daily added to the hemisphere, and the weather becomes hotter. The same reason may be given for the greatest cold generally following the shortest day, with a considerable interval. All these circumstances, however, depend much on the atmospheric circumstances of the year.

The preceding explanation does not serve for the tropical climates, the days and nights are here so nearly equal throughout the year, that seasons are caused more by the effect of the winds (which are very regular, and depend mainly on the sun's position) than by changes in the direct action of the sun's light and heat. The seasons are not a summer and a winter, so much as recurrences of wet and dry periods, two in each year.

With regard to the quantity of heat received in a day, it might be expressed, so far as it is not modified by the atmosphere, in a formula depending on the latitude of the place and the sun's declination. It will be enough to say that this formula shows that, the sun being in the equator, the day's heat in different places is as the cosine of the latitude; and that for all places at the equator, the day's heat for different days is as the cosine of the sun's declination.

The different distances at which the earth is from the sun, at different times of the year, do not affect the heat received in a given portion of the orbit. The sun is nearest to the earth in our midwinter, but for that reason the winter is shorter, since the earth moves more rapidly when nearer to the sun. The compensation is exact, for the quantity of heat received at any one moment, while the radius of the earth's orbit moves through any small angle, is greater or less in the inverse proportion of the square of that radius. But the time of describing that angle is less or greater in the direct proportion of the same square. Consequently the heat actually received by the earth in the two halves of its orbit is the same in both.

SEAT (in a church). [PEW.]

SEAWORTHINESS. [SHIPS.]

SEBACIC ACID. [SEBACIC GROUP.]

SEBACIC GROUP. A small class of chemical compounds belonging to the pelargonic series in Gerhardt's arrangement. The principal member is sebacic acid

Sebacic acid ($C_{20}H_{16}O_6$, 2HO) or *pyroleic acid* is always obtained when oleic acid or an oil containing oleic acid is distilled. It is most advantageously prepared by the action of a hot and very strong solution of caustic potash upon castor oil. The ricinolic acid of the castor oil is thus split up into sebacic acid, caprylic alcohol, and free hydrogen. Sebacic acid is soluble in hot water, and crystallises out from a boiling solution of the sebate of potash, produced as just indicated, on the addition of hydrochloric acid. It forms white lamellar or acicular crystals, of the appearance of benzoic acid; is very soluble in alcohol, ether, or oils; reddens litmus paper; melts when heated to 260° Fahr., and at a higher temperature sublimes. Nitric acid converts it into succinic acid.

Sebacic acid is bibasic, forming neutral *sebates* of the formula 2MO, $C_{20}H_{16}O_6$; and acid salts containing MO,HO,$C_{20}H_{16}O_6$. The alkaline salts are nearly all crystalline and soluble in water; from them the other sebates are prepared by double decomposition. *Sebate of methyl* or *methyl sebacic ether* contains $C_{20}H_{16}(C_2H_3)_2O_8$; by contact with ammonia it gradually yields *sebamide* ($C_{20}H_{20}N_2O_4$) in crystalline grains, the mother liquor containing *sebamic acid* ($C_{20}H_{19}NO_6$).

Ipomic acid seems to be identical with sebacic acid. Jalap (ipomea purga) resin yields rhodeoretic acid when acted on by bases, and rhodeoretic acid furnishes ipomic acid on being oxidised by nitric acid. The fusing point of ipomic acid is 40 degrees below that of sebacic acid, but in every other respect it resembles the latter body.

SEBAMIC ACID. [SEBACIC GROUP.]

SEBAMIDE. [SEBACIC GROUP.]

SEBAT (in Hebrew, שְׁבָט), is the fifth month of the civil year of the Jews. The name is mentioned in the 7th verse of the 1st chapter of Zechariah, where it is called the eleventh month, reckoning from the vernal equinox, at which season the Jews anciently began their year. It is called Sabat in the Apocrypha, at 1 Macc. xvi. 14. The name is found at Palmyra written as in Hebrew, and at Balbek it was written Σοβαδ. Sebat has thirty days; its place in the year varies from January to February, and in 1860 it began on the 25th of January and ended on the 23rd of February. In 1861 it began on the 12th of January and ended on the 10th of February. A fast is mentioned in some calendars on the 4th day of Sebat, for the wickedness of Israel after the death of Joshua, and another on the 23rd day, in memory of the war between the tribe of Benjamin and the rest of the nation, related in the 20th chapter of Judges; but these fasts are observed very partially, if at all.

SEBIN. ($C_{32}H_{30}O_{16}$). The sebate of glycerin. It is neutral and crystalline, and is transformed by oxide of lead into sebacic acid and glycerin.

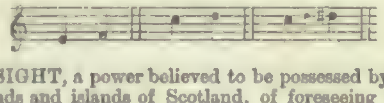
SECALE CORNUTUM. [ERGOT.]

SECANT, a line which cuts another; also a term in TRIGONOMETRY.

SECEDERS. The origin and history of the Seceders from the Established Church of Scotland will be found briefly stated in the article UNITED PRESBYTERIAN CHURCH, that being the name adopted by the religious fellowship which includes the greater number of Seceders. The *Synod of United Original Seceders*, the only body which retains the name Seceders in its official designation, professes the same doctrine and discipline as the United Presbyterian Church, but maintains the principle of a national church, and also that of national religious vowing or covenanting. The Original Seceders number about 30 congregations, forming 4 presbyteries. Since the disruption in 1843 [FREE CHURCH OF SCOTLAND], many of those known as Original Seceders and Associate or Old Light Burghers, have joined the Free Church, on the ground of its being, in their judgment, the true National Reformed Church of Scotland.

SECOND, the sixtieth part of a minute, whether of time or of angular measure. [ANGLE; TIME.] For the derivation of this word, see SCRUPLE.

SECOND, an interval in music, a discord, the ratio of which is 9 : 8. Of seconds there are three kinds: the minor second, or semitone, as E F; the major second, C D; and the extreme sharp second, C D; Ex.:—



SECOND-SIGHT, a power believed to be possessed by some persons in the highlands and islands of Scotland, of foreseeing future events, especially of a disastrous kind, by means of a spectral exhibition of the persons whom these events respect, accompanied with such emblems as denote their fate.

Jamieson says, "Whether this power was communicated to the inhabitants of the highlands and islands of Scotland by the northern nations, who so long had possession of the latter, I shall not pretend to determine; but traces of the same wonderful faculty may be found among the Scandinavians. Isl. *ramskygn* denotes one who is endowed with the power of seeing spirits: 'qui tali visu præter naturam præditus est, ut spiritus et dæmones videat, opaca etiam visu penetret.' Verel. Ind. The designation is formed from *ramm-ur*, viribus pollens, and *skygn*, videns; q. e. powerful in vision."

Dr. Johnson, in his journey to the Western Islands of Scotland, carefully examined the questions of the second-sight; but neither he nor Dr. Beattie could find sufficient evidence of its reality.

In Sir John Sinclair's 'Statistical Account of Scotland,' vol. iii., 8vo., Edinb., 1792, the minister of Applecross, in the county of Ross, speaking of his parishioners, says, "with them the belief of the second-sight is general."

In MacCulloch's 'Western Islands of Scotland,' 8vo., Lond., 1819, vol. ii., the author says, "To have circumnavigated the Western Isles without even mentioning the second-sight would be unpardonable. No inhabitant of St. Kilda pretended to have been forewarned of our arrival. In fact it has undergone the fate of witchcraft; ceasing to be believed, it has ceased to exist."

In the Erse the second-sight is called *Taisch*.

SECONDARY, a name given to any circle on the sphere with reference to another circle: if the latter be called primary, the former is secondary when it passes through the poles of the primary. [Sphere.]

SECONDARY COIL, CURRENTS, &c. [Magneto-Electricity.]

SECRETARY (French, *Secrétaire*), one entrusted with the secrets of his office or employer; one who writes for another. Its remote origin is the Latin *secretum*. The phrase "notarius secretorum" is applied by Vopiscus ('Div. Aurelianus') to one of the secretaries of the emperor Aurelian. This appellation was of very early use in England: Archbishop Becket, in the reign of Henry II., had his "secretarius;" although the person who conducted the king's correspondence, till the middle of the 13th century, was called his clerk only, probably from the office being held by an ecclesiastic. The first time the title of "secretarius noster" occurs is in the 37th Hen. III., 1253.

SECRETARY OF STATE. The office of secretary of state is one of very ancient date, and the person who fills it has been called variously "the king's chief secretary," "principal secretary," and, after the Restoration, "principal secretary of state." He was in fact the king's private secretary, and had custody of the king's signet. The duties of the office were originally performed by a single person, who had the aid of four clerks. The statute 27 Henry VIII., c. 11, regulating the fees to be taken by "the king's clerks of his grace's signet and privy seal," directs that all grants to be passed under any of his majesty's seals shall, before they are so sealed, be brought and delivered to the king's principal secretary or to one of the clerks of the signet. The division of the office between two persons is said to have occurred at the end of the reign of Henry VIII., but it is probable that the two secretaries were not until long afterwards of equal rank. Thus we find Sir Francis Walsingham, in the time of Queen Elizabeth, addressed as her majesty's principal secretary of state, although Dr. Thomas Wilson was his colleague in the office. Clarendon, when describing the chief ministers at the beginning of the reign of Charles I., mentions the two secretaries of state, "who were not in those days officers of that magnitude they have been since; being only to make despatches upon the conclusions of councils, not to govern or preside in those councils." Nevertheless the principal secretary of state must, by his immediate and constant access to the king, have been always a person of great influence in the state. The statute 31 Henry VIII., c. 10, gives the king's chief secretary, if he is a baron or a bishop, place above all peers of the same degree; and it enacts that if he is not a peer, he shall have a seat reserved for him on the woolsack in parliament; and in the Star Chamber and other conferences of the council, that he shall be placed next to the ten great officers of state named in the statute. He probably was always a member of the privy council. Cardinal Wolsey in his disgrace earnestly implores Secretary Gardiner (afterwards bishop of Winchester), whom he addresses as a privy councillor, to intercede for him with the king. (Ellis's 'Letters,' vol. ii.) Lord Camden, in his judgment in the case of Entick *v.* Carrington (11 Hargrave's 'State Trials,' p. 317), attributes the growth of the secretary of state's importance to his intercourse with ambassadors and the management of all the foreign correspondence of the state, after the policy of having resident ministers in foreign courts was established in Europe. Lord Camden indeed denies that he was anciently a privy counsellor.

The number of secretaries of state seems to have varied from time to time: in the reign of George III. there were often only two; but there are now five principal secretaries of state, whose duties are divided into five departments, namely, for home affairs, foreign affairs, for war, for the colonies, and a fifth, first appointed in 1858, for the management of the affairs of India. They are always made members of the privy council and the cabinet. They are appointed (without patent) by mere delivery to them of the seals of office by the sovereign. Each is capable of performing the duties of all the departments, and the offices are all so much counted to be one and the same, that if removed from one secretaryship of state to another, a member of the House of Commons does not vacate his seat.

To the secretary of state for the home department belongs the maintenance of the peace within the kingdom, and the administration of justice so far as the royal prerogative is involved in it. All patents, charters of incorporation, commissions of the peace and of inquiry, pass through his office. He superintends the administration of affairs in Ireland. The secretary for foreign affairs conducts the correspondence with foreign states, and negotiates treaties with them, either through British ministers resident there, or personally with foreign ministers at this court. He recommends to the crown ambassadors, ministers, and consuls to represent Great Britain abroad, and countersigns their warrants. The secretary for the colonial department performs for the colonies the same functions that the secretary for the home department performs for Great Britain. The secretary for war has the management of the army, in which he has the assistance of the commander-in-chief. Each is assisted by two under-secretaries of state, nominated by himself; the one being usually permanent, the other dependent upon the administration then in power. The secretary for India has one under-secretary, and the assistance of a council. There is likewise in each department a large establishment of clerks appointed by the principal secretary.

The power to commit persons on suspicion of treason is incidental to the office of principal secretary of state—a power which, though long exercised, has been often disputed. It is not necessary here to give the arguments on both sides; they are discussed with great care by Lord Camden in the case above cited (Entick *v.* Carrington), which was one of the numerous judicial inquiries arising out of the dispute between the Crown and John Wilkes at the beginning of the reign of George III. The conclusions to which Lord Camden comes are—that the secretary of state is not a magistrate known to the common law; that the power of commitment for state offences, which he has for many ages exercised, was used by him as an immediate delegation from the person of the king, a fact which may be inferred, among other things, from the debates in parliament in the time of Charles I., when Secretary Cook claimed the power on that ground; that nevertheless courts of justice must recognise this power, inasmuch as there has been constant usage of it, supported by three judicial decisions in favour of it since the Revolution, namely, by Lord Holt in 1695 (Rex *v.* Kendal and Rowe); by Chief Justice Parker in 1711 (Queen *v.* Derby); and by Lord Hardwicke in 1734 (Rex *v.* Earbury). In a more recent case (King *v.* Despard, 1798), Lord Kenyon says, "I have no difficulty in saying that the secretaries of state have the right to commit," and he hints that Lord Camden felt too much doubt on the subject.

There is also a chief secretary for Ireland, resident in Dublin (except when parliament is sitting), and having always an under-secretary there. He corresponds with the home department, and is under the authority of the lord lieutenant. His office is called that of secretary to the lord lieutenant; but it is analogous to the office of secretary of state. He has sometimes, though very rarely, been a member of the cabinet.

SECT (from the Latin *Secta*). Two accounts are given of the origin of this word. By some persons it is represented as a derivative of *sequ-or* (*secu-tus*), "to follow." By others it is derived from *sec-o* (*sec-tus*), "to cut." It is in this case, as in many similiar instances, not easy to decide between the pretensions of the two; and it is far from being improbable that some persons may have used the word as a derivative from one verb, and others as derived from the other.

The *sects* of philosophers in ancient times seem rather to have been persons who were *followers* of some distinguished teacher, than persons *cut off* from any general mass. But when we come to the word in its now more common and familiar use, namely, as denoting a particular community of Christians, the idea then predominates of *separation, cutting off*, over that of *following*. Thus no one thinks of calling the Roman Catholic church a sect: and none, except it was designed to disparage and dishonour it, would call the English Protestant church a sect. But when we descend below it, we then see smaller religious communities, who are *cut off* from a church, either by their own act, or by some supposed or real act of usurpation and unchristian tyranny on the part of the larger community. Thus the Quakers are a sect, the Anabaptists are a sect, the Methodists are a sect, and the Independents and English Presbyterians now are sects, though some of these were for a time in existence without falling under the description of a sect, being still incorporated in the church, in which they sought to accomplish certain reforms. In other systems there are smaller bodies of sectaries.

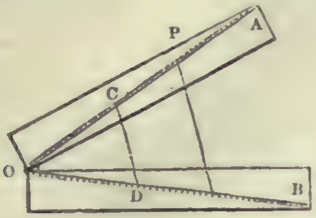
SECTION, the curve made by the intersection of two surfaces. In the graphical arts it means generally a plane section, and most frequently a vertical section, the horizontal section being called the plan. In architectural designs, the longest vertical section is usually called the elevation, the term section being restricted to vertical sections which are perpendicular to the elevation.

SECTOR (Geometry), the figure made by two straight lines which meet, and a curve which cuts them both. The most common is the circular sector, made by two radii of a circle and the arc which they include. If r be the radius in linear units, and θ the angle measured in *theoretical* units [Angle], the area of the sector is $\frac{1}{2} r^2 \theta$ square units; but according as the angle is expressed in degrees and fractions of a degree, in minutes and fractions of a minute, or in seconds and fractions of a second, the area is found by the first, second, or third of the following formulæ:—

$$\frac{r^2\,\theta^\circ}{2 \times 57{\cdot}29578} \qquad \frac{r^2\,\theta'}{2 \times 3437{\cdot}747} \qquad \frac{r^2\,\theta''}{2 \times 206264{\cdot}8}$$

SECTOR (drawing instrument), an instrument invented by Gunter, which has the appearance of a small carpenter's rule, marked with scales in every part; the greater number of these scales not being laid down parallel to the edges of the rule, but converging towards the pivot on which the moving arm of the rule turns while the instrument is opened. Only these converging scales properly belong to the sector; the others are merely laid down for convenience on such blank spaces as are left by the converging or sectorial scales.

The sector is a large number of pairs of compasses packed up into one, and most explanations of the instrument attempt to describe them all in one. It will, however, be more convenient to separate one pair of compasses from the rest, and to describe its use. Each piece of the ruler is marked with the same scales. Take one of these scales, O A, and that which corresponds to it, O B; then A O B is a pair of compasses which can be opened or shut at pleasure. Suppose two scales, say of chords, to be laid down on O A and O B, which are chords of 90°,



O P and O Q being radii, or chords of 60°. If O P be four inches, we have then before us two scales of chords with the radius of four inches actually laid down, and any chords might be taken off them as from a common scale: for instance, if the marks of 35° be at C and D, then either O C or O D is the chord of 35° to a radius of four inches. But suppose it required to find the chord of 35°, not to a radius of four inches, but to one of 3·61 inches. We know that

$$4 : 3{\cdot}61 :: \text{ch. } 35° \text{ (rad. 4)} : \text{ch. } 35° \text{ (rad. } 3{\cdot}61\text{)};$$

and the fourth term of this proportion is to be found. Now this may be done with sufficient accuracy, and without any drawing, as follows:— Take a common pair of compasses, and open them to 3·61 on a subdivided scale of inches. Then open the sector until the points of the compasses are made to fall on P and Q, which, if the sector open rather easily, may be done very quickly. We have then $PQ = 3{\cdot}61$ inches, and C D is the chord of 35° to that radius; for by similar triangles

$$\begin{gathered} OP : PQ :: OC : CD; \\ \text{or, } 4 : 3{\cdot}61 :: \text{ch. } 35° \text{ (rad. 4)} : CD; \\ \text{whence, } CD = \text{ch. } 35° \text{ (rad. } 3{\cdot}61\text{)}. \end{gathered}$$

Take the compasses then, and fixing one point at C, make the other fall on D; the distance C D may then be transferred with the compasses to the paper, or to the scales of inches, according as construction or arithmetical estimation is required.

The scales usually laid down upon the two sides of common sectors, such as are constructed upon a foot ruler, are:—

1. A line of *polygons*, marked POL., showing the sides of polygons inscribed in a circle. And since the side of the hexagon is the radius of the circle, the radius of the scale is the distance from O to the figure 6. Thus, to inscribe a polygon of ten sides in a circle of two inches radius, open the sector until 6 and 6 on the counterpart polygon scales are two inches apart: then the distance from 10 to 10 on the same scales will be the side of the figure required.

2. A line of *chords*, as above described, the radius being the chord of 60°. But it is to be noted that upon the common sector the whole length O A of the scale is only the chord of 60°, so that angles above 60° do not appear. To construct an angle of more than 60°, first set off 60° on the circle drawn by means of the radius, and take the chord of the remainder from the sector. We think that the sector might be usefully copied in this respect on the common scales: giving all the length which the proposed scale will allow, to the chord of 60°, instead of that of 90°.

3. A line of *sines*, the radius of which is the sine of 90°. Thus, to find the upright side of a right-angled triangle having an hypothenuse of 3·41 inches, and an angle of 32°, open the sector until 90° and 90° on the counterpart lines of sines are 3·41 inches apart; then the distance from 32° to 32° on the same lines will be the side required.

4. A line of *secants*, usually extending to about 75°, the radius of course being the secant of 0°. This scale is blank from O to 0°.

5. A first line of *tangents*, from 0° to 45°, the radius being the tangent of 45°, or the whole length of the rule.

6. A second line of tangents, on a smaller scale, beginning at 45° and proceeding to about 75°, the radius being the tangent of 45°, or the distance from O to the beginning of the scale.

7. A line of equal parts for operations answering to finding a fourth proportional to three numbers. Thus to find a fourth proportional to 36, 47, and 53, make 36 and 36 on the counterpart scales fall as far apart as from O to 47; then the distance from 53 to 53 on the same scales, measured on the scale, will show the fourth proportional.

To write on the applications of the sector would be to make a treatise on graphical trigonometry: one instance may suffice. It is required to calculate the formula

$$76 \times \frac{\sin. 59°}{\sin. 38°}$$

On the counterpart lines of sines make 38° and 38° (by opening the sector) fall as far apart as from O to 59° on the same scale; then the distance from 76 to 76 on the counterpart lines of equal parts will show, on that line of equal parts, the numerical value of the result required. Or make 38° and 38° on the counterpart lines of sines fall as far apart as from O to 76 on the line of equal parts: then the distance from 59° to 59° on the counterpart lines of sines will show the result required on the scale of equal parts.

The sector becomes an incorrect instrument, comparatively, when a great opening is required, and also when the result is much greater than the data from which it is produced. So much accuracy of construction is necessary, that those to whom the instrument is often really useful (not many, we suspect) should rather procure the larger ones, which are manufactured by the best instrument-makers, than be content with the six-inch lines which are found in the common cases of instruments. The sector is an instrument which requires much more care than the common scale, and in the use of which expertness can be gained by nothing but practice. Each scale is a pair of parallel lines with cross divisions; and it is important to note that the compasses must be applied to the inner of the parallel lines in every case. Also when the compasses are in the hand, with one point laid on one of the scales, the other scale being about to be moved to bring the other point of the compass on the right division of the counterpart scale, take care to hold the compasses only by that leg which is laid down on the scale.

SECTOR, ZENITH. [ZENITH SECTOR.]

SECULAR, a name given to those variations in the planetary motions which are of long duration, so that their periods are better expressed in centuries than years.

SEDATIVES are agents which produce a direct depression of the action of the vascular system, with little sensible evacuation. They differ from narcotics, inasmuch as their depressing effects are not preceded by any obvious excitement or increased action of the heart and arteries. Whether they act primarily on the heart itself, or secondarily by a previous influence on the nervous system, is not clearly ascertained. Some, such as the infusion of tobacco, and hydrocyanic acid, appear to destroy completely the sensibility of the heart, so that it no longer responds to the stimulus of the blood; but how this effect results is altogether unknown. Oxalic acid, when the dose is large, seems also to paralyse the heart; while in less quantities it operates differently. [OXALIC ACID.] The peculiar mode of action of the articles entitled to be considered as pure sedatives has been detailed under the respective heads of DIGITALIS, HYDROCYANIC ACID, NICOTIANA, &c., and need not be repeated here. The medical employment of these formidable agents should never be had recourse to without competent authority and superintendence; but as many cases of poisoning result from their accidental or criminal administration, it is needful to observe that the greatest promptness is requisite in the administration of appropriate remedies. Vital stimulants, such as ammonia and brandy, are the best; and electricity or galvanism may be resorted to after the others.

Sulphuretted hydrogen, when breathed, injected into a vein of the rectum, or even applied to the skin, acts as a sedative, and in a small quantity can occasion death. It is largely disengaged from many decomposing substances, such as exist in stagnant pools, ditches, drains, and cesspools. Proximity to these produce effects more or less serious according to the intensity of the gas. Even one of its compounds, hydro-sulphuret of ammonia, is a potent sedative. Cold, when extreme, likewise acts as a sedative, but its mode of action has been already explained under BATHING. Chloroform and other anæsthetics may be considered sedatives of the nerves of sensation.

SEDILIA, in ecclesiastical architecture, the seats on the south side of the chancel, near the high altar, in Roman Catholic churches, in which the officiating priest and his attendant ministers sit during a portion of the performance of high mass. In many of our old collegiate and parish churches the sedilia still remain. The few that are extant of Norman date belong to the middle or latter half of the 12th century. In Pointed Gothic of every period they are frequent, and are almost always made a very ornamental feature. Usually they are recessed in the wall, like niches, and covered with canopies, which in some instances are lofty and much ornamented, resembling tabernacle work: but sometimes the sedilia are quite plain, little more in fact than stone benches. Commonly the sedilia are three in number, divided from each other by slender pillars, and gradated, that nearest the altar (intended for the priest) being the highest; but they are met with of varying numbers—from one to five—and all level, or with only the priest's seat raised above the others.

SEDITION (from the Latin *seditio*). It is stated that in many of the old English common law writers treason is sometimes expressed by the term Sedition; and that when law proceedings were in Latin, *seditio* was the technical word used in indictments for treason, till it was superseded by the word *proditio*.

Sedition does not appear to be very exactly defined. It is stated to comprehend contemptuous, indecent, or malicious observations upon the crown or government, whether made in words only, or in writing, or by tokens (which last term must comprehend pictures or drawings), calculated to lower the sovereign in the opinion of the subjects or to weaken his government. All these offences fall short of treason; but they are considered crimes at common law, and punishable by fine and imprisonment.

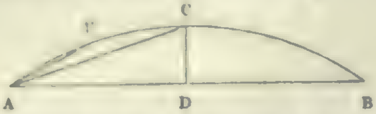
There are also statutes against particular acts of sedition, such as seditious libels. [LAW, CRIMINAL.] There are also various acts against societies established for seditious and treasonable purposes, and against seditious meetings and assemblies.

The Roman sense of *seditio* (*sed* or *se*, and *itio*, a going apart, a separation) is properly a disunion among the citizens, a riot, or turbulent assemblage of people for the purpose of accomplishing some object by violence or causing fear. It was included among other forbidden acts in the Lex Julia de Majestate. ('Dig.,' 48, tit. 4.) It is often used in connection with "tumultus" and "turba," and the three terms seem to have the same signification.

(Rein, *Römisches Criminalrecht*, p. 522.)

SEDUCTION. [PARENT AND CHILD.]

SEGMENT (part cut off), a term which, in its general sense, needs no explanation. It is, in mensuration, most frequently applied to the part cut off from a circle by a chord, and the measurement of this segment of a circle is the only point for which reference is likely to be made to the word. Let A B be the segment of a circle, and C and D the middle points of its arc and chord. The segment A C B is easily expressed by the angle which the arc subtends at the centre: if this angle (measured in the theoretical units [ANGLE]) be θ, and the radius r, the number of square units in the segment is



$$\frac{r^2}{2}(\theta-\text{sin.}\ \theta).$$

But when a segment is actually to be measured in practice, it usually happens that the radius is not given, and the circle is too large to measure it conveniently. In that case the middle point C must be found, and A B and A C must be measured, as also C D. This being done, the length of the arc A B can be found with great exactness from the formula "one third of the excess of eight times A C over A B, or $\frac{1}{3}$ (8 A C − A B)." This formula errs only about one foot out of 80 (always giving the arc a little too small) in a whole semicircle, and the error diminishes nearly as the fourth power of the arc; thus at half a semicircle the error is about one foot out of $2^4 \times 80$, or 1280 feet; at one-third of a semicircle it is only about one foot out of $3^4 \times 80$, or 6480 feet, and so on. Another formula of the same sort, but so close to the truth that no measurements could ever be taken in practice sufficiently exact to make its inaccuracy appreciable, is the following: find E the middle point of A C, and measure A E; then the arc is very nearly (but a little less than)

$$\frac{\text{AB}+256\ \text{AE}-40\ \text{AC}}{45}.$$

The error here is less than one foot out of 390 on the whole circle, and diminishes with the sixth power of the arc.

Taking the arc from one or other of these methods, the area of the segment is then to be found as follows:—Determine R, the radius, from $\text{AC}^2 \div 2\ \text{CD}$, and compute

$$\frac{\text{R}\times\text{Arc}-\text{AD}\,(\text{R}-\text{CD})}{2},$$

which gives the area required. This formula may be reduced to

$$\frac{\frac{2}{3}\,\text{AC}^2\,(2\ \text{AC}+\text{AD})-\text{AD}^3}{\text{CD}}.$$

Thus (to take an instance of Bonnycastle's) if AD = 12, AC = 13, whence CD = 5 (all feet), we have for the area of the segment

$$\frac{\frac{2}{3}\times169\times38-1728}{5}=82{\cdot}533 \text{ square feet.}$$

Another approximate rule is (giving somewhat too little)

$$\frac{\text{CD}\,(12\ \text{AD}+8\ \text{AC})}{15},$$

which is more exact than the preceding. The error is only one per cent. when the segment is a semicircle, and it diminishes with the seventh power of the subtended angle nearly.

It answers well enough for rough purposes, and particularly when the segment is small, to consider the arc of the circle as being part of a parabola, and to take two-thirds of the rectangle under A B and C D for the area.

SEIGNORAGE. [CURRENCY.]

SEIGNORY. [TENURE.]

SEISIN is a term properly applied to estates of freehold only, so that a man is said to be *seised* of an estate of inheritance or for life, and to be *possessed* of a chattel interest, such as a term of years. This distinction does not appear to have existed in the time of Bracton; at least he uses the two words as identical in meaning ("possessio sive seisina multiplex est,' lib. ii., fol. 38).

The seisin of the tenant of a freehold is the legal possession of the land. It is actual seisin, called seisin in deed, when he has corporeal possession of the land, or, as Bracton expresses it, "corporalis rei detentio: corporis et anima cum iuris adminiculo concurrente." It is seisin in law when lands have descended to a person, but he has not yet actually entered into possession of them, and no person has usurped the possession. When an estate of inheritance is divided into several estates, as for instance an estate for life, and a remainder or reversion in fee, the tenant in possession has the actual seisin of the lands; but the persons in remainder or reversion have also seisin of their respective estates.

In the conveyance of land by feoffment, which is now, however, almost unknown, the delivery of the possession, or livery of seisin, as it is termed, is the efficient part of the conveyance. [FEOFFMENT.]

Seisin in deed is obtained by actually entering into lands, and an entry into part in the name of the whole is sufficient; by the receipt of rents or profits; and by the actual entry of a lessee to whom the lands are demised by a person who is entitled to but has not obtained actual possession.

Seisin may also be acquired under the Statute of Uses, 27 Hen. VIII., which enacts that when any person shall be seised of any lands *to the use*, &c., of another, by reason of any bargain, sale, feoffment, &c., the person having the use, &c., shall thenceforth have the lawful seisin, &c., of the lands in the same quality, manner, and form as he had before in the use.

A disseisin supposes a prior seisin in another, and a seisin by the disseisor which terminates such prior seisin. To constitute a disseisin, it was necessary that the disseisor should not have a right of entry; the disseisee should not voluntarily give up his seisin; and that the disseisor should make himself the tenant of the land, or in other words, should put himself, with respect to the lord, in the same situation as the person disseised. "But," it is well remarked (Co. Litt., 266 b, Butler's note), "how this substitution was effected, it is difficult, perhaps impossible, now to discover. From what we know of the feudal law, it does not appear how a disseisin could be effected without the consent or connivance of the lord; yet we find that the relationship of lord and tenant remained after the disseisin. Thus after the disseisin the lord might release the rent and services to the disseisee; might avow upon him; and if he died, his heir within age, the lord was entitled to the wardship of the heir." But the doctrine of disseisin is in many respects very obscure, and at present of very little practical importance.

SEISMOLOGY, from *σεισμος*, an earthquake (that is, a movement like the shaking of a sieve), and *λόγος*, a discourse, the science of earthquakes; and SEISMOMETRY, from the same, and *μετρέω*, to measure, the science of the mensuration of all the phenomena of earthquakes which can be expressed in numbers, or by their relation to the co-ordinates of space. The origin of these new departments of science has been stated in the article EARTHQUAKES, in which the physical definition of an earthquake was also given, agreeably to the researches of Mr. Robert Mallet. We now proceed to state some of the elements of seismology, and the nomenclature applied to them, premising that the basis of this is formed by the adjectives *seismal* and *seismic*, both signifying what has relation to an earthquake. An earthquake being the transit of a wave of elastic compression through the earth, there are three elements of this earthquake-wave, namely, the velocity of transit, the velocity of the wave-particle (or wave itself [WAVE]), and the direction of motion at each point of the *seismic area*, or tract on the earth's surface within which the earthquake is felt. From the last element may be determined, 1st, the point upon the earth's surface vertically over the centre of effort, or focal point, whence the earthquake impulse was delivered; and 2nd, the depth below the surface (or rather sea-level) of the focal point itself. The line passing through both these points is the *seismic vertical*. The wave starts from the focal point with one normal and two transversal vibrations, and may be imagined transferred outwards, in all directions, in concentric spherical shells, whose volume at the same phase of the wave is constant. The shock reaches the surface directly above the focal point vertically; but, for all points around that, it emerges with angles becoming more and more nearly horizontal as the distance measured on the surface increases. The intersecting circle of any one shell with the surface, which is that of simultaneous shock, is the *coseismal line*, or crest of the earth-wave: circular if in a homogeneous medium, more or less distorted if in a heterogeneous one (such as constitutes the various geological formations of the earth's crust), but always a closed curve. The *meizoseismal area* is that in which the shock is experienced in the greatest degree, and *isoseismal areas* are those in which it is felt at the same time. A *seismic region* is a tract of the earth's surface, the earthquakes of which have some community of origin, manifested by their simultaneous occurrence. *Seismic energy* is the total amount of force exerted in earthquakes at a given period, or in a given space, or with relation to any other element of the subject. *A chrono-seismic curve*, laid down from the records of earthquakes, the ordinate of which is that of epoch, and the abscissa that of *seismic intensity* (in this case the force of a given earthquake), expresses the progression of seismic energy in time.

Every object displaced by an earthquake shock is in fact a *seismometer*, and in the selection and arrangement of suitable objects for such displacement, so as to give the required evidence of the velocity and directions of the motion, consists the practical science of seismometry. For particulars of the construction and principles of complete self-registering seismometers, we must refer to Mr. Mallet's Fourth Report to the British Association; but we proceed to notice some extemporaneous seismometers with which important observations may be made, under circumstances in which fixed instruments cannot be appealed to. The elements necessary to be recorded, Mr. Mallet states, in his article 'On Observation of Earthquake Phenomena,' in the third edition of the 'Admiralty Manual of Scientific Inquiry,' are such as will enable us to calculate, in order to obtain finally the actual elements of the wave itself, as stated above—1, the direction in azimuth of the wave's motion upon the earth's surface, and also its direction of emergence at the points of observation. 2, Its velocity of transit upon the surface. 3, Its dimensions and form—that is, its amplitude and altitude.

If a common barometer be moved a few inches up and down by the hand, the column of mercury will be found to oscillate up and down in the tube in directions opposite to the motions of the instrument, the range of the mercury depending upon the velocity and range of motion of the whole instrument. A barometer fixed to the earth, therefore, if we could unceasingly watch it, would give the means of measuring the vertical element of the shock-wave; and if we could lay it down horizontally, it would do the same for the amplitude, or horizontal element. This we cannot do; but the same principle may be put into use by having a few pounds of mercury and some glass tubes bent into the form of the letter L, sealed close at one end, and open at the other; together with some common barometer tubes, having the open end turned up like an inverted syphon. The instruments to be constructed of these are of the nature of fluid pendulums. They are superior to common solid pendulums, where the dimensions of the shocks are small; but where these are great and very violent, heavy solid suspended pendulums will be found more applicable. The length of the seconds pendulum for the latitude of Greenwich will always be desirable.

Mr. Mallet thus describes a solid pendulum, of easy construction, which will answer several important purposes of seismometry. "Fix a heavy ball, such as a four-pound shot, at one end of an elastic stick, whose direction passes through the centre of gravity of the ball: a stout rattan will do. Fix the stick vertically in a socket in a heavy block of wood or stone, and adjust the length above the block as near as may be to that of the seconds pendulum for Greenwich. Prepare a hoop of wood, or other convenient material, of about 8 inches diameter; bore four smooth holes through the hoop in the plane of its circle, and at points 90° distant from each other: adjust through each of these a smooth round rod of wood (an uncut pencil will do well), and make them, by greasing, &c., slide freely, but with slight friction, through the holes. Secure the hoop horizontally at the level of the centre of the ball by struts from the block, and the ball being in the middle of the hoop, slide in the four rods through the hoop until just in contact with the ball. It is now obvious that a shock, causing the ball to oscillate in any direction, will move one or more of the rods through the holes in the hoop, and that they will remain to mark the amount of oscillation.

"A similar apparatus, with the pendulum-rod secured horizontally (wedged into the face of a stout low wall, for example), will give the vertical element of the wave. Two of these should be arranged, one north and south, the other east and west. One objection to this and all apparatus upon the same principle is, that as the centre of elastic effort of the pendulum-rod never can be insured perfectly in the plane passing through the centre of gravity of the ball, for every possible plane of vibration, so an impulse in a single plane produces a conical vibration of the pendulum, and hence the ball deranges the position, more or less, of the index rods which are out of the true direction of shock. Moving the apparatus by hand, and a little practice in observation of its action, will, however, soon enable a pretty accurate conclusion as to the true line of shock to be deduced from it."

The observer must record minutely the dimensions and other conditions of such apparatus, to enable calculations as to the wave of scientific value to be made from his observations of the range of either fluid or solid pendulums. "A common bowl partly filled with a viscid fluid, such as molasses, which, on being thrown by oscillation up the side of the bowl, shall leave a trace of the outline of its surface, has been often proposed as a seismometer. This method has many objections; it can only give a rude approximation to the direction of the horizontal element; but as it is easily used, should never be neglected as a check on other instruments. A common cylindrical wooden tub, with the sides rubbed with dry chalk and then carefully half filled with water or dye stuff, would probably be the best modification."

Such instruments and contrivances as those now described, suffice to give the direction of transit of the earth-wave, and its dimensions. Its rate of progress or transit over the shaken country remains to be observed; and wherever it may be possible to connect three or more such instruments, at moderately distant stations, say from fifteen to thirty miles apart, by galvanic telegraph wires, so as to register at one point the moment of time at which each instrument was affected, the best and most complete ascertainment of transit rate may be expected. On the entire subject of extemporaneous seismometry, we must again refer the intending observer to Mr. Mallet's article in the 'Admiralty Manual' before referred to.

Since the publication of the article EARTHQUAKES, Mr. Mallet has applied the method of investigating their phenomena, announced in his reports published in those of the British Association, to the earthquake of December 16, 1857, noticed in that article, the greatest that has occurred in Italy since that of 1783; having personally examined its effects. He has incorporated the results in an elaborate report read to the Royal Society on the 24th of May, 1860, and of which an abstract is given in vol. x. of the Society's 'Proceedings,' p. 486–494, the report itself being reserved for the 'Philosophical Transactions.'

From that abstract the following particulars are derived, being the result of the first exact investigation of the phenomena of a great earthquake. It was felt over nearly the whole of the Italian peninsula, south of Terracina in the States of the Church, near the Neapolitan frontier, about 56 miles south-east from Rome, and of Gargano, on the Adriatic. Its area of greatest destruction, or meizoseismal area, within which nearly all the towns were wholly demolished, was an oval, whose major axis was in a direction north-west and south-east nearly, and about twenty-five geographical miles in length by ten in width. The first isoseismal area beyond this, within which buildings were everywhere more or less prostrated and people killed, is within an oval of about sixty geographical miles by thirty-five; the second isoseismal is also an oval within which buildings were everywhere fissured, but few prostrated, and few or no lives lost. The third isoseismal embraces a greatly enlarged area, within which the earthquake was everywhere perceived by the unassisted senses, but did not produce injury. A fourth isoseismal was partially traced, within which the shock was capable of being perceived by instrumental means, and which probably reached beyond Rome to the northward.

The seismic vertical, Mr. Mallet determined from the independent and concurrent evidence of above seventy separate wave-paths, was close to the village of Caggiano, near the eastern extremity of the valley of the Salaris. The depth of the focal point below the sea-level, that is, the *mean* focal depth was found to be about 5¾ geographical miles. From all the information, observed and calculated, it was deduced that the *focal-cavity*, within which the seismic energy originated, was a curved lamellar cavity, or fissure, of about three geographical miles in depth by nine in length, with an inclined vertical section, and a mean focal depth (or depth of its central point of surface) of 5¾ miles below the level of the sea, as just stated. The probable horizontal form of the cavity, when laid down upon a map, co-ordinates with the existing lines of dislocation of the country in a remarkable manner. Mr. Mallet, it may here be remarked, assumes the force that acted within this cavity to have been due to steam of high tension, either suddenly developed or suddenly admitted into a fissure rapidly enlarged by rending.

The most trustworthy of the observations of time correspond with considerable exactness, and give a velocity of transit of the wave of shock upon the surface, of between 700 and 800 feet per second. Strictly speaking this is the velocity at which the *wave-form* was propagated from point to point. The velocity of the wave itself, or of the *wave-particle*, was in round numbers between 13 and 14 feet per second in the direction of the wave-path. Mr. Mallet points out a remarkable relation between this velocity and that recorded for the earthquake of Riobamba, as the greatest whose effects have been observed. The height due to the velocity of this wave is to the altitude of Vesuvius as that due to the velocity recorded of the Riobamba wave is to the mean height of the volcanic shafts of the Andes, and more especially to the height of the volcanic vents nearest to Riobamba. [VOLCANOS.] The wave of shock, of course, decays in relation to superficial distance from the seismic vertical. The amplitude of the wave slowly and slightly increases, and its velocity decreases. In the case of the Italian earthquake under investigation, the lowest velocity at nearly 30 miles from the seismic vertical was still about 11⅙ feet per second. The total modifying effects of this earthquake on the earth's surface were insignificant. No great sea wave accompanied it; nor was such possible, the focal point being inland. Mr. Mallet examined with care more than 150 miles of sea-coast, as well as river-courses, for evidence of any permanent elevation of land having taken place concurrently with the earthquake, but found none. This is an important point, because geologists and travellers have often ascribed elevations of the land to earthquakes, or to a succession of earthquake-shocks directed upon the same spot; but "earthquakes," Mr. M. observes, "cannot produce elevations, although the latter have been known to have taken place about the same time as earthquakes, and in the same region." . . . . "The functions of elevation and depression," of an earthquake, "are limited solely to the sudden rise and as immediate fall, of that limited portion of the surface through which the great wave is actually passing momentarily."

The works and memoirs cited in this and in the article EARTHQUAKE, will make the student acquainted with the entire available literature on the subject of earthquakes.

SELECT VESTRY. [VESTRY.]

SELENALDINE. [THIALDINE.]

SELENE (Σελήνη), the Moon, was worshipped as a goddess by the ancient Greeks. She is generally represented as the sister of Helios, or the Sun; sometimes as his daughter, and occasionally as his wife, and the mother of the four Seasons. She is also said to have had children by Zeus and several others. The story of Endymion, whom she caused to fall into a perpetual sleep that she might unseen gaze upon his beauty and enjoy his embraces, is well known from the use made of it by the poets. By him she is said to have been the mother of fifty daughters. She was believed to drive her chariot through the heavens during the night. (Hom., 'Hymn.,' xxxii. 7.) Her chariot is usually represented in ancient works of art drawn by two horses, whereas that of Apollo was drawn by four. She is only distinguished from Artemis by being more fully draped. She is frequently represented in bas-reliefs on sarcophagi, hovering in the air over the sleeping Endymion. In course of time the attributes of Selene were given to Artemis, and the latter was represented as the goddess of the moon; but these deities were originally distinct. [Artemis.]

SELENETHYL. [Selenium.]

SELENIC ACID. [Selenium.]

SELENIOUS ACID. [Selenium.]

SELENITE. [Calcium. *Sulphuric Acid and Lime.*]

SELENIUM (Se) a nonmetallic, solid, elementary body, discovered in 1818 by Berzelius in the iron pyrites of Fahlun; the sulphur procured from which was used at Gripsholm in the manufacture of sulphuric acid. In the latter a deposit was formed of a red colour, which, on account of the peculiar odour that it emitted, was supposed, though erroneously, to contain tellurium, the origin of which name suggested that of *selenium*, from Σελήνη, the moon, for the new substance. The discoverer considered it a metal, but it is now classed with the nonmetallic elements.

Selenium has been found hitherto only in small quantity; it occurs in the pyrites of Anglesey, and probably in that of many other places: sulphide of selenium has been detected among the volcanic products of the Lipari Isles; and in the Harz it has been met with, combined with lead, silver, and some other metals.

Magnus extracts selenium from the native sulphide by treating it with binoxide of manganese, by the oxygen of which the sulphur is converted into sulphurous acid, which escapes in the gaseous form, while the selenium either sublimes in its pure state or as selenious acid.

Selenium is a brown somewhat transclucent solid when in mass. It is inodorous and insipid, moderately hard, may be readily scratched with a knife, is brittle as glass, and easily reduced to powder. Its fracture is conchoidal. Its sp. gr. varies from 4·30 to 4·8, on account of the cavities which it frequently contains. It is a bad conductor of heat, and a non-conductor of electricity. It softens at 212°, and may be drawn out into fine threads, which are transparent, and of a red colour by transmitted light. When heated rather higher, it becomes fluid, and boils at 650°, emitting a vapour, which is inodorous, and of a deep yellow colour; this in close vessels condenses in dark globules of a metallic lustre, or of a cinnabar-red colour, according as the space in which it collects is small or large. Water does not dissolve selenium; it is however soluble in the fat oils and melted wax, but not in the volatile oils. The equivalent of selenium is 39·75.

Oxygen and Selenium combine in three different proportions, forming oxide of selenium, selenious acid, and selenic acid.

Oxide of Selenium (SeO) may be formed by heating the selenium in a limited quantity of atmospheric air, and by washing the product to separate the selenious acid formed with it. It emits a very strong smell resembling that of decayed horse-radish, so that 1-50th of a grain of selenium is sufficient when burnt to scent a room of considerable size, and this is a characteristic property of selenium. Oxide of selenium is gaseous, colourless, very slightly soluble in water, and quite devoid of acid properties.

Selenious acid (SeO_2) may be prepared by passing a current of oxygen gas over heated selenium; but it is more conveniently obtained by digesting selenium in nitric acid or nitro-hydrochloric acid till dissolved, and then evaporating the solution to dryness.

This acid is colourless, and when strongly heated sublimes, and condenses unchanged in the form of acicular crystals, which possess distinctly marked acid properties. It attracts moisture from the air and is consequently very soluble in water; a hot saturated solution yields crystals on cooling; it is also soluble in alcohol, and has when heated an acrid odour. It forms salts with bases, which are called *Selenites.*

Many substances which have strong affinity for oxygen decompose selenious acid; this is the case with sulphurous acid and phosphorous acid, and when the former is added to a solution of selenious acid, a red powder is precipitated, which is pure selenium, and sulphuric acid is at the same time formed. An alkaline sulphate produces a similar effect; hydrosulphuric acid is also decomposed by and decomposes selenious acid, and a yellow compound is formed and precipitated, which is sulphide of selenium.

Selenic Acid ($HO.SeO_3$) may be prepared by fusing selenium, a selenide, or selenite, with nitrate of soda. The seleniate of soda obtained is to be decomposed by nitrate of lead, and the insoluble seleniate of lead precipitated is to be decomposed by a current of hydrosulphuric acid, which throws down the lead as a sulphide. The selenic acid remains in solution, with some excess of hydrosulphuric acid, which is to be expelled by ebullition.

Selenic acid is liquid, colourless, inodorous, of an oleaginous consistence, and very acid; it attracts moisture from the air, and always retains about 12·4 per cent. of water, which cannot be expelled without decomposing the acid. It may be heated to 536° without decomposition, but at 554° it is rapidly converted into oxygen and selenious acid. When concentrated at a temperature of 329°, its sp. gr. is 2·524, and it gradually increases up to the temperature of 545°, when it becomes 2·625. When mixed with water, much heat is evolved. Its salts are called *Seleniates.* Zinc and iron are dissolved by this acid with the evolution of hydrogen gas, and copper with the formation of selenious acid.

Seleniate of soda ($NaO, SeO_3 + 10$ aq.) occurs in large crystals like those of Glauber's salt. *Seleniates of lime* ($CaO, SeO_3 + 2$aq.) and of *nickel* ($NiO, SeO_3 + 6$aq.) resembles the corresponding sulphates. *Seleniate of Cadmium* ($CdO, SeO_3 + 2$aq) differs both in composition and crystalline form from the sulphate of cadmium, the crystals also lose an equivalent of water on being heated to 212° Fahr.

Hydrogen and Selenium (HSe) unite to form hydroselenic acid or seleniuretted hydrogen. It is easily obtained by the action of diluted sulphuric acid upon selenide of potassium, or of iron. This gas is colourless, has a disagreeable odour, and so powerfully irritates the membrane lining the nose as to excite symptoms of catarrh, and destroy the sense of smelling for some hours. Water readily dissolves this gas: the solution is at first colourless, but after a time it acquires a reddish hue; it gives a brown stain to the skin, and reddens litmus paper. When exposed to the atmosphere it is decomposed, its hydrogen being absorbed by oxygen, and the selenium is deposited. It decomposes the solutions of many metallic salts, selenides of the metals being precipitated.

Chlorine and Selenium combine when the gas is passed over the selenium; heat is evolved, and a brown chloride is obtained, which is liquid; it is heavier than water, not very volatile, and by the action of water is eventually decomposed, and resolved into selenious and hydrochloric acids and selenium.

This *dichloride* (Se_2Cl) may be converted into a *bichloride* by exposure to excess of chlorine. It is a white solid compound which is volatilised when heated, and condenses in small crystals. It is decomposed by water.

Sulphur and Selenium (S_2Se). A definite compound of these is formed by passing hydrosulphuric acid gas into a solution of hydroselenic acid; the fluid assumes a yellow colour, becomes turbid, and a precipitate is formed, though but slowly, unless a little hydrochloric acid be added. When exposed to heat this disulphide of selenium becomes red and viscid, and at high temperatures may be distilled without decomposing.

Phosphorus and Selenium combine when the selenium is dropped into melted phosphorus; the product is a red substance, but it does not appear that any definite compound of these bodies is formed.

Selenethyl or *selenium-ethyl.* [Ethyl, *selenide of ethyl.*]

Selenium forms *selenides* with most of the metals, and the selenide of lead is one of the most abundant of the native compounds which occur in the Hartz. [Lead, in Nat. Hist. Div.]

The characteristic properties of selenium are those of tinging the flame of the blowpipe of a light blue colour, and emitting an acrid vapour, when heated in the air, which has the peculiar smell of decayed horse-radish.

SELENIURETTED HYDROGEN. [Selenium.]

SELF-REGISTERING INSTRUMENTS. In the determination of scientific data, it is of the utmost importance that the instruments of observation be as free from error as possible, or that the sources and amount of error be accurately known. It is further necessary that the means of observation be irreproachable, and, if possible, continuous. Where an instrument requires to have its indications recorded night and day, a large staff of observers is required, and they are liable to error, even when carefully trained to their work. [Equation, Personal.] The magnetic instruments at the Greenwich Observatory were formerly observed every two hours; but the results were of course liable to error, and occasionally the magnetic variations were too rapid and transient to be recorded. Hence attempts—and many of them successful ones—have been made from time to time to make instruments of observation record their own results. We have seen under Anemometer the contrivances for registering the direction and pressure of the wind, together with the amount of rain; and under Barometer some of the mechanical arrangements are stated for making that instrument self-registering. The maximum and minimum thermometers in ordinary use will be described under Thermometer. Our object in this place is briefly to notice the vast improvement that has taken place of late years in consequence of the application of photography to the purposes of self-registration. A description of the apparatus employed for the self-registration of the changes in position of the declination magnet, of the horizontal force magnet, and of the vertical force magnet, will show the nature of the arrangements. A prepared photographic paper is wrapped round a cylinder, the axis of which is placed parallel to the direction of movement to be registered, and the cylinder is turned round at a uniform rate by clockwork. The light is supplied by a gas-lamp furnished with a copper chimney, in which is a small slit capable of adjustment by a screw. It is on the breadth of this slit that the breadth of the register-line depends. This light falls upon a concave speculum, which rests in a stirrup connected with the magnet to be observed, so as to partake of all its angular movements. The pencil of light is reflected from the mirror to a plano-convex lens, placed near to, and parallel with, the axis of the cylinder, which lens condenses the line of light to a definite spot of light on the paper. The source of light being fixed, it is evident that the movements of the spot of light will correspond with those of the magnet, to the right and left in a horizontal plane in the case of the declination magnet and horizontal force magnet, and up and down in a vertical plane in registering the movements of the vertical force magnet. Hence, as the cylinder is constantly being moved round by clockwork, there is traced upon the paper a curve of which the abscissa, measured in the direction of a line round the cylinder, is proportional to the time, while the ordinate, measured in the direction of the axis of the cylinder, is proportional to the movement of the magnet. A base-line, from which to measure the ordinates, is traced upon the paper by the action of a spot of light proceeding from another gas-lamp placed near the cylinder and passing through a slit fixed to the carrier of the cylinder.

In the photographic registration of the barometer, the instrument is arranged in the siphon form, and a float, resting on the surface of the mercury in the shorter limb, hangs in a notch on the short arm of a delicately poised lever. At the end of the long arm of this lever is an opaque screen containing a small aperture, through which a pencil of light passes. Now it is evident that, as this screen moves up and down with the oscillations of the mercury, a line will be traced on the photographic paper by the pencil of light transmitted by the screen. There is also an arrangement for tracing a base-line on the photographic paper. The cylinder carrying the sensitive paper is mounted on a turn-table, which is carried round by the hour-hand of a clock placed concentrically beneath it. The paper is covered by a second cylinder to prevent it from becoming dry, during the twenty-four hours that the apparatus remains in action. The cylinders are also covered with a blackened zinc case to prevent all light from falling on the paper, except that from the pencils which describe the register and the base line.

In the photographic registration of the thermometer and psychrometer, the bulbs of the instruments are freely exposed beneath a table on which is a revolving cylinder covered with sensitive paper, while the stems pass up through the table, and are placed between the cylinder and a source of light, which, by means of a cylindrical lens, falls on the stem of the thermometer in a narrow vertical line, and, passing through that part of the bore which is above the mercury, blackens the sensitive paper. The boundary between the affected and the unaffected parts of the paper indicates the position of the mercury in the stem of the instrument. Fine wires are placed across the slit through which the light passes, and coarser wires are attached to every tenth degree, as well as to the points 32°, 54°, 76°, and 98° Fahr. The shadows of these wires protect the portion of the paper on which they fall from the action of the light, so that the darkened surface of the paper is traversed by a series of parallel pale lines, and the relative positions of the broad and narrow lines show the temperature indicated by the register. The whole of the apparatus is protected by an outer wind- and water-tight zinc case.

SELINUNTINE MARBLES. [Sculpture.]

SEMAPHORE. [Telegraph.]

SEMIBENZIDAM. Synonymous with *Azophenylamine.* [Organic Bases.]

SEMIBREVE, a character in music, sometimes nearly circular in form, but more commonly elliptical. Ex.:

This is adopted as the measure-note in music; the other five characters that indicate duration, as minim, crotchet, &c., being considered as proportional parts of it.

SEMICOLON. [Punctuation.]

SEMINAPHTHALIDUM. [Naphthalic Group. *Nitronaphthylamine.*]

SEMIQUAVER, a musical character, formed of a crotchet with two hooks added at the extremity of the stem, and is in duration $\frac{1}{16}$ of a semibreve. Ex.:

SEMITIC LANGUAGES. [Aramæan, or Aramaic Language; Hebrew Language; Language.]

SEMITONE, an interval in music, whose ratio is 16 : 15, as C C♯.

SENATUS, according to the etymological meaning of the word, is "an assembly of elders," and this is the sense which the Roman writers attach to the earliest senate of Rome. The number of senators in the Greek republics, as well as at Rome, always bore a certain relation to the number of tribes of which the state was composed. Hence, as long as Attica was divided into four tribes, the number of senators was 400; and when Cleisthenes divided the country into ten tribes, he increased the number of senators to 500. As long as Rome only comprehended one tribe, the Latins of the city on the Palatine, their senate consisted of only 100 members. After the accession of a second tribe, the number of senators was raised to 200; and when a third tribe was united with them, the number of senators was increased to 300. Each of the three Roman tribes was divided into ten curiæ, and each curia into ten gentes, and the same number of decuries, containing, according to Göttling, parts of several gentes, and made for purposes of representation. At the head of each gens there was a decurio, who, according to Niebuhr, by virtue of this office was a senator, or a representative of his gens in the senate. But Walter ('Gesch. des Röm. Rechts,') justly observes that the age of a decurio, who was at the same time a military officer, and consequently must always have been a young man and able to bear arms, does not appear to be consistent with the age and duties of a senator. It is much more probable that each decury elected from its own body one by whom it was represented in the senate. Each curia was thus represented by ten senators, who were called a "decuria senatorum" (Liv., i. 7). At the head of this decuria senatorum was a curio, and the ten heads of the decuries, when the senate consisted of only 100 members, or ten decuries, were the "decem primi," from among whom the king chose one as princeps senatus. It appears that when the Ramnes and Tities became united, and the senate consisted of twenty decuries, the ten decuries of the Ramnes with their decem primi still retained for a time a kind of superiority over the Tities. (Dionys. Hal., ii.; Plut., 'Num.,' 3.) The senators representing the Ramnes gave their votes first, and the princeps senatus was chosen from among them alone. But the first two tribes must soon have been placed on a footing of equality, so that some of the decem primi, as well as the princeps senatus, might belong to either of the tribes. (Dionys., *l. c.*) After the union of the third tribe, the senators representing the first two are supposed by Niebuhr to be the "patres majorum gentium," and those representing the third to be the "patres minorum gentium." Göttling ('Gesch. d. Röm. Staatsv.) on the other hand considers the "patres minorum gentium" to have been the noble plebeians whom Tarquinius Priscus admitted into the three old tribes, and who, in consequence of this, became eligible to the senate. (Cic., 'De Rep.,' ii. 20.) The patres minorum gentium had at first, as Niebuhr (ii., p. 114) supposes, no right to speak in the senate, but merely voted by *going over* to either party; and he therefore conceives that they were the "senatores pedarii." (Gellius, iii. 18; Dionys., vii., p. 453.) This name of senatores pedarii might in subsequent times, when all the senators had equal rights, be applied to all senators indiscriminately, as it was their general custom to vote by discessio, or a division. All writers agree that Tarquinius Priscus raised the number of senators to 300, but the manner in which this was effected is stated differently. Cicero (*l. c.*) says that the king doubled the existing number of senators (which would accordingly have been 150), while others (Liv., i. 35; Dionys., iii., p. 199) state that he merely added 100 senators to the existing number of 200. Niebuhr ingeniously reconciles these two statements by the supposition that before the time of Tarquinius Priscus some of the gentes of the first two tribes had become extinct, though it does not follow that the number of the extinct gentes amounted exactly to fifty. But if, as we have supposed, the senators were not elected by each gens, but by a decuria, Niebuhr's supposition must fall to the ground, as it cannot be conceived how decuries could become extinct, as they might be formed in such a manner that one large gens would comprehend several decuries, while smaller ones united in forming one decury, and thus were always able to make up a certain number of decuries. The statement of Cicero appears to rest upon a misconception. (Göttling, p. 228.) Servius Tullius did not introduce any change in the composition of the senate, but in the reign of the last king, Tarquinius Superbus, the number of senators is said to have become greatly diminished, as many of them were put to death, and others were sent into exile. These vacancies however were filled up immediately after the establishment of the republic by electing into the senate the principal plebeians of the equestrian order. Livy (ii. 1) ascribes this completion to L. Junius Brutus; Dionysius (v., p. 287), Plutarch ('Popl.,' 11), and Festus (*s. v.* "qui patres"), to Valerius Publicola. The number of these new plebeian senators is said to have been 164, but this is utterly incompatible with the subsequent history of Rome. The new plebeian senators were called Conscripti, in contradistinction to the patrician senators, or patres; hence the mode of addressing the whole senate "patres conscripti," that is, "patres et conscripti." The word patres, although in later times used to designate senators in general, was originally another name for patricians. (Liv., ii. 1; Fest., *s. v.* "adlecti;" Niebuhr, i., p. 327, &c.) The number of 300 senators henceforth remained unaltered for several centuries. C. Gracchus was the first who attempted an alteration. Livy ('Epit.,' lib. 60) says that he wished to increase the senate by adding 600 equites, but this seems a mistake, and the reading is probably corrupt. Plutarch ('C. Gracch.,' 5, &c.) says that he added 300 equites to the 300 senators, and transferred to this body the Judicia (publica). All the other writers who mention these events (see the passages in Göttling, p. 237, note 3) do not allude to an increase in the number of senators, but merely state that he transferred the Judicia to the equites. A similar attempt was made by the tribune Livius Drusus. (Appian, 'Civil.,' i. 35.) Sulla added 300 equites to the senate, and thus increased its number to 600. [Sulla, in Biog. Div.] Four hundred senators were after this time present in a case when many were absent. (Cic. 'ad Att.', i. 14.) Julius Cæsar increased the number of senators to 900, and elected men of the lowest rank into the senate. (Dion Cas., liii. 47.) This mode of filling up vacancies or increasing the number of senators with freedmen and common soldiers was continued after the death of Cæsar, and at one time there were more than 1000 senators. (Suet., 'Aug.,' 35.) Augustus again reduced the number to 600. (Dion Cass., liv. 14.) Respecting the number of senators during the empire, we possess no direct information. During the latter period of the empire the number of senators appears to have become greatly diminished.

The senators were from the earliest times elected for life. Their name indicates that originally they were men of advanced age, but the exact age at which a man might become a senator during the kingly period is not mentioned. During the latter centuries of the republic, however, the age seems to have been fixed by some Lex Annalis, as the ætas senatoria is frequently mentioned. But as a quæstor after the year of his office might be made a senator, and as the legitimate age for the quæstorship was twenty-five years, we have reason to believe that a person who had attained the age of twenty-six might be elected a senator. It might, however, be inferred from Polybius (vi. 17) that this was not the case till a person had completed his twenty-seventh year. As regards the election of persons into the senate during the kingly period, Livy (i. 8) and Festus (*s. v.* 'Præteriti Senatores') state that it was a privilege of the kings. Dionysius (ii., p. 85), though he involves himself in difficulties by supposing that the three tribes were already united when the senate consisted of only 100 members, is undoubtedly right in stating that the senators were not appointed by the kings. (Niebuhr, i. p. 338.) The senators were elected by the decuries, and thus were real representatives of the curies, or a select body of the populus. The plebeians, who were afterwards admitted into the senate by Tarquinius Priscus, and after the banishment of the kings, must either have been incorporated with the patrician gentes, or their number must have been very small, for the first instance of a plebeian senator at Rome is Sp. Maelius, in 439 B.C.; and a second is P. Licinius Calvus, in 400 B.C., although the latter may have held the office of quæstor, and so have got admission into the senate. Niebuhr (i. p. 527, &c.) thinks that long before the institution of the censorship there must have been a time when the senators were chosen by the curies, and not by the subdivisions of the curies, and that each curia elected ten senators. He founds this supposition upon the Lex ovinia tribunicia mentioned by Festus (*s. v.* 'Præteriti Senatores'). But as regards the time, Niebuhr is manifestly wrong, which he himself seems to have felt afterwards (ii., p. 403, note 885); for the Lex Ovinia refers to the censors, whom it directed to elect into the senate "optimum quemque curiatim." (Compare Göttling, p. 345, &c.; Walter, 'Gesch. d. Röm. R,' p. 100, &c.) During the early period of the republic, the right of electing persons into the senate belonged to the consuls, dictator, and military tribunes. But all the curule magistracies, as well as the quæstorship, conferred upon those persons who had held them the right of being elected into the senate. (Liv., xxii. 49, "unde in Senatum legi deberent.") The quæstorship conferred this right probably from the earliest times, as it did in the time of Sulla [QUÆSTOR], and this circumstance explains why the patricians opposed the eligibility of the plebeians to the quæstorship. After the establishment of the censorship, the election of persons into the senate was wholly in the hands of the censors. All curule magistrates, that is, consuls, prætors, curule ædiles, and censors, had by virtue of their office a seat in the senate, and might speak on any subject. After their office was over they retained this right, but without being real senators. Now vacancies in the senate were filled up at every lustrum, and it was only on this occasion that the censors might elect those ex-magistrates into the senate whose conduct was unblemished. Hence we have to distinguish between two kinds of senators, real senators (senatores), and such as were allowed "dicere sententiam in senatu." (Fest. *s. v.* 'Senatores.') The old decem primi senatus are no longer mentioned. The honour of princeps senatus, which during the kingly period had been combined with the office of custos urbis, and had been granted by the kings for life, was afterwards united with the office of prætor urbanus, or with that of a military tribune (Liv., vi. 6), and only lasted for one year. After the establishment of the censorship, this honour was conferred by the censors, and at first upon the eldest among the living ex-censors; but afterwards upon any one whom the censors thought most worthy. (Liv., xxvii. 11.) If the censors thought a person who had held a curule office unworthy of being a senator, they passed over him ("præteribant:" Fest., *s. v.* 'Præteriti'); but this seems to have seldom occurred with persons who had held a curule office. (Liv., xxxiv. 44; xxxviii. 28.) The plebeians as an order never obtained the right of being eligible as senators; but as soon as the great offices of the republic became accessible to the plebeians, their claims to the dignity of senator could not be disputed. As, therefore, the quæstorship, consulship, censorship, and prætorship, were one after the other thrown open to the plebeians, their numbers in the senate likewise continued to increase. At last (perhaps in the year 131 B.C.; Walter, p. 165, note 156), even the tribunes of the people, after having before acquired the right to convoke the senate and to take part in its deliberations, gained by the Plebiscitum Atinium the rights of real senators. (Gellius, xiv. 8.) On certain occasions a dictator was created for the purpose of electing new members into the senate. (Liv., xxiii. 22, &c.) M. Fabius Buteo, in 216 B.C., not only elected such men as had held curule offices, but also such as had been plebeian ædiles, tribunes, quæstors, and persons who had distinguished themselves as soldiers. The senate, which at first had been the representative of the populus, thus gradually became the real representative of the people; for although the censors or a dictator were the electors, yet, either by custom or by law, they always elected such men as had held offices given by the people, so that it was in fact the people who elected the members of the senate, and the Roman senators themselves viewed their dignity as from the people. (Cic. 'pro Sext.,' 65; 'c. Verr.,' iv. 11; 'pro Cluent.,' 56.) This also accounts for the fact that the members of the great colleges of priests, with the exception of the flamen dialis (Liv., xxvii. 8), had no seats in the senate; and for the same reason it was a disputed point whether the præfectus urbi should have a vote in the senate (Gellius, xiv. 8), for in the colleges of priests vacancies were filled up by co-optatio of the members themselves, and the præfectus urbi was appointed by the consuls, and none of them derived their power from the people. In the time of Cicero, however, this appears to have been altered, for we find that pontiffs might at the same time be senators. (Cic. 'ad. Att.,' iv. 2.) Notwithstanding all this, however, the senate, down to the end of the republic, preserved in a great measure its original character; it remained an aristocratic body.

During the republic we do not hear that any property qualification was required for a senator (Plin., 'Hist. Nat.,' xiv. 1), though the senators must generally have belonged to the wealthiest classes. There is indeed a passage in Livy (xxiv. 11) from which it has been inferred that previous to the second Punic war a senatorial census was instituted (Niebuhr, iii., p. 406); but the words of Livy are too vague to admit of such an inference, and probably refer only to the fact that senators were among the wealthiest Romans, and were consequently able to make greater sacrifices to the republic than other persons. Göttling (p. 346) concludes from Cicero ('ad Fam.,' xiii. 5) that Cæsar was the first who instituted a senatorial census, but the passage of Cicero is even less conclusive than that of Livy. The first to whom the introduction of a senatorial census is expressly ascribed is Augustus. He first fixed it at 400,000 sesterces, but afterwards increased it to 800,000, and at last to 1,200,000 sesterces. (Suet., 'Aug.,' 41; Dion Cass., liv. 17, 26, 30; lv. 13.) If a senator lost or spent so much of his property as to fall short of the senatorial census, he was obliged to withdraw from the senate, unless the emperor connived, or supplied the deficiency. (Tacit., 'Annal.,' ii. 48; xii. 52; xv. 28; 'Hist.,' iv. 42; Suet., 'Aug.,' 41; 'Tiber.,' 47; Dion Cass., lx. 11.) The senatorial age was fixed by Augustus at twenty-five years (Dion Cass., lii. 20), and the names of the senators were entered on a list called 'Album Senatorium.' (Tacit., 'Annal.', iv. 42; Dion Cass., liv. 13; lv. 3.) Augustus reduced, as we have seen, the number of senators to 600, and cleared their body from the unworthy persons who had been admitted before his time. He also improved the senate by electing into it the most distinguished citizens of municipia and colonies, and even provincials. (Tacit., 'Annal.' iii. 55; xi. 25; Suet., 'Vespas.,' 9.) Such senators of course resided at Rome, and, with the exception of those who belonged to Sicily or Gallia Narbonnensis, they were not allowed to visit their former homes without a special permission of the emperor. (Tacit., 'Annal.,' xii. 23; Dion Cass., lii. 42; lx. 25.) At a later period these foreign senators were required to purchase a certain amount of landed property in Italy. (Plin., 'Epist.,' vi. 19.) The emperors also assumed the right of convoking the regular as well as extraordinary meetings of the senate (Dion Cass. liii. 1; liv. 3), although the consuls, prætors, and tribunes continued to enjoy the same privilege. (Tacit. 'Hist.,' iv. 39; Dion Cass., lvi. 47; lix. 24.)

Senators were never allowed to carry on any mercantile business. About the commencement of the second Punic war, however, some senators seem to have entered into mercantile speculations; and a law was passed, notwithstanding the opposition of the senate, that no senator should be allowed to possess a ship of more than 300 amphoræ in tonnage (Liv., xxi. 63), this being thought sufficiently large to convey to Rome the produce of their possessions abroad (comp. Cic. 'c. Verr.,' v. 18); from which passage it is clear that this law was not always observed. No one moreover could be elected senator whose parents were not free men by birth (ingenui). The first violation of this custom was attempted by the censor Appius Claudius Cæcus, who elected into the senate the sons of freedmen. (Liv., ix. 29 and 46; Aurel. Vict., 'De Vir. Illustr.,' 34.) But this election was considered illegal. Towards the close of the republic such proceedings appear to have been rather common. (Dion Cass., xl. 63; iii. 47; Horat.. 'Sat.,' i. 6, 21.) If a senator was struck from the lists of senators by the censors, he was not disqualified for any of the great state offices, but he might still obtain them, and thus find his way back to the senate. (Cic. 'pro Cluent.,' 46; Dion Cass., xxxviii., 30; xliii. 52; comp. "Nota" in 'Dict. of Greek and Rom. Antiq.')

The regular meetings of the senate (*senatus legitimus*) during the republic were held on the calends, nones, and ides of every month. (Cic. 'ad Quint. Frat.,' ii. 13.) Extraordinary meetings (*senatus indictus* or *edictus*) might be convoked on any day, provided it was not a dies comitialis, or a dies ater. Augustus decreed that a senatus legitimus should only be held twice every month, on the calends and on the ides; that during the months of September and October, only a small number of senators, drawn by lot, should attend; and that their attendance should be sufficient to enable the body to transact business. (Suet., 'Aug.,' 35; Dion Cass., lv. 3.) What number of senators was necessary in order to constitute a legal meeting is uncertain: on some occasions, however, as we see from the senatus consultum de Bacchanalibus (Liv., xxxix. 18), a decree could not be made unless there were one hundred senators present. Sometimes also it was found necessary to enforce the attendance by a multa, or a pignoris captio. (Cic., 'Philip.,' i. 5.) Augustus increased the severity of the law in this respect. (Dion Cass., liv. 18; lv. 3; lx. 11.) At first he required the presence of four hundred members to constitute a full assembly; but he afterwards reduced this number; and at a later period, the presence of seventy, or even fewer senators, was sufficient. (Lamprid., 'Alex. Sev.,' 16.)

The places of meeting for the senate (curiæ or senacula) were always templa, that is, places consecrated by the augurs; and there were originally three of them: 1, the temple of Concordia, between the Capitol and the Forum; 2, a place near the Porta Capena; and 3, a place near the temple of Bellona, outside of the city. (Fest., *s. v.* 'Senacula.') Subsequently, however, meetings of the senate were held in a great many other places. The place near the temple of Bellona was principally used for the purpose of giving audience to generals who returned from their campaigns, and were desirous to obtain a triumph; also to receive foreign ambassadors, especially such as were sent by an enemy, and were not allowed to enter the city. Towards the close of the republic, it was decreed that during the whole month of February the senate should give audience to foreign ambassadors on all days on which a senate could be held, and that no other business should be transacted in the senate until the affairs of the foreign ambassadors were settled. (Cic. 'ad Quint. Frat.,' ii. 13; 'ad Fam.,' i. 4.)

In the earliest times of Rome, the right of convoking the senate belonged to the kings or their vicegerents, and they also introduced the subjects for discussion. The princeps senatus, or custos urbis, put the question. The patres majorum gentium voted first, and the patres minorum gentium last. (Cic., 'De Rep.,' ii. 20.) During the republic the senate might be convoked by the consuls, the dictator, the prætor, the tribunes of the people, the interrex, or the præfectus urbi: the decemvirs, military tribunes, and the triumviri rei publicæ constituendæ, likewise exercised this right; but the persons who intended to convoke the senate generally offered sacrifices to the gods and consulted the auspices. (Gellius, xiv. 7.) The assembled senators appear to have sat in a regular and fixed order: first, the Princeps senatus; then the Consulares, Censorii, Prætorii, Ædilicii, Tribunicii; and lastly, the Quæstorii. In this succession they also gave their votes. (Cic., 'Philip.', v. 17; xiii. 14; 'Ad. Att.', xii. 21.) The majority always decided. This mode of voting remained the same during the empire. (Plin., 'Epist.', viii. 14; ix. 13; Tacit., 'Annal.', iii. 22; xi. 5.) The business was conducted as follows: the magistrate who had convoked the senate was always the president, and he laid before the assembly the subjects for discussion, opening the business with the words, "Quod bonum, faustum, felix, fortunatum sit; referimus ad vos, patres conscripti." After the subject of discussion was explained, the president asked the senators for their opinion in the order in which they sat. (Liv., i. 32; ix. 8.) If the consules designati were present, they had the precedence even of the princeps senatus. (Sallust., 'Cat.', 50; Cic. 'Philip.', v. 13.) If any of the members dissented from the measure proposed, he might express his opinion freely, or propose an amendment to it. After the discussions were over, the president called upon the members to vote; and the majority, which decided the question, was ascertained either by numeratio or discessio. A sitting of the senate was, generally speaking, not continued after sun-set; but in unexpected or very urgent cases the business was carried on by candle-light, and even till after midnight. Augustus introduced the custom that every senator, before he took his seat, should offer incense and a libation to the god in whose temple the meeting was held. (Suet., 'Aug.', 35.) During the time of the empire one of the consuls seems always to have presided in the senate, and the emperors only when they were consuls (Plin., 'Epist.', ii. 11); but by virtue of their tribunician power, they might at any session introduce any subject they pleased (Dion Cass., liii. 32), and subsequently this privilege was granted to them by an especial decree (jus relationis). (Vopisc., 'Prob.', 12; J. Capitol., 'Pertin.', 5; 'M. Antonin.', 6; Lamprid., 'Alex. Sev.', 1.) The measures or propositions made by an emperor were introduced in the form of written orations (orationes principum), and read in the senate by one of his quæstors. (Suet., 'Aug.', 65; Tit., 6, Tacit., 'Annal.', xvi. 27.) The manner of conducting the business was on the whole the same as in the time of the republic. But when magistrates were elected in the senate, the votes were given by ballot. (Plin., 'Epist.', iii. 20; xi. 5.) Previous to the time of Cæsar the transactions of the senate were not kept or preserved in any regular way. (Plut., 'Cat. Min.', 23.) Cæsar was the first who ordained that all the transactions of the senate (acta senatus) should be kept and made public. (Suet., 'Cæs.', 20.) These transactions were written under the superintendence of one of the senators (called "ab actis," or "à cura actorum"), by scribes appointed for the purpose. (Tacit., 'Annal.', v. 4, &c.; Spart., 'Hadr.', 3.) In case the business of the senate was carried on in secret, the senators themselves officiated as clerks. (Jul. Capitol., 'Gord.', 12.)

Down to the end of the republic the senate of Rome partook more or less of the character of a body representing the people: it was, as Dionysius says (v., p. 331, vi. p. 408), the head and soul of the whole republic, or the concentrated intelligence and wisdom of the whole nation. It is chiefly to the consistency, wisdom, and energy with which the senate acted during a long period that Rome was indebted for her greatness and her success.

During the kingly period the kings acted according to the determinations of the senate, and the kings had only the executive. The subjects on which the senate decided before they came before the people, comprehended the whole internal administration of the state, legislation, finance, and war. On the death of a king the senate proposed the new candidate to the comitia by means of the interrex. (Liv., i. 17.) At the establishment of the republic no change appears to have been made in the power and authority of the senate. The senate and the people had the sovereign power. At first all measures, whether relating to the administration or legislation, originated with and were prepared by the senate; but this power was afterwards considerably diminished by the attacks of the tribunes of the people. In many cases the original state of things became reversed, inasmuch as laws might originate with the people, and only require the sanction of the senate; or might have the power of law even without this sanction. [Tribunus.] A still more formidable blow was inflicted upon the power of the senate when the tribunes obtained the right of invalidating its acts by their intercessio. [Tribunus.] The power which the senate exercised during the republic, when the tribunes did not intercede, may be comprised under the following heads:—

1. The senate had the control of the public treasury (ærarium) ('Polyb.', vi. 13); the accounts of all the revenues were laid before the senate, and no part of the public money could be expended without their consent. Hence no consul or magistrate could raise an army, or keep it at the expense of the state, unless he was authorised by the senate. [Scipio, in Biog. Div.]

2. Crimes committed in Italy, such as treason, conspiracies, poisoning, and murder, belonged to the cognizance of the senate; moreover, if any private individuals or any of the allied towns of Italy had disputes among themselves, if they had done anything deserving punishment, or if they required assistance or a garrison, all this was within the power of the senate. (Polyb., vi. 11; comp. Liv., xxx. 26.) In cases, however, where a judicial sentence was required, the senate appointed a person, but did not pronounce sentence itself. (Cic., 'De Off.', i. 10; Val. Max., vii. 3, 4.)

3. All ambassadors sent from Rome, and all commissioners charged with the regulation of the affairs of a newly conquered province, were nominated by the senate, and the ambassadors themselves were in many cases members of the senate. All foreign ambassadors communicated with the Roman senate. (Polyb., *l. c.*; and Livy, in numerous passages.) Treaties concluded with foreign nations by a Roman general required the sanction of the senate.

4. The senate assigned to the consuls and prætors their respective provinces [Provincia], and the senate might at the end of a year propose the prolongation of their imperium.

5. The senate decreed all public thanksgivings (supplicationes) for victories obtained by the generals of the republic; and the senate alone could confer on a victorious general the honour of a triumph or of an ovatio. (Liv., v. 23; Cic., 'Philip.', xiv. 5.)

6. The senate in times of great danger could delegate unlimited power to the consuls; and this was done by the formula, "videant consules nequid respublica detrimenti capiat." The senate had also the supreme superintendence in all matters of religion, and decided whether the worship of new gods was to be adopted or not. [Serapis.]

During the empire the senate lost its former character, for the emperors became the sovereign, and the senate was a subordinate power, and little more than a high court of justice. Respecting the provinces of the senate, see Provincia. The senators, however, were always looked upon as persons of the highest rank. Vacancies were filled by the emperor at discretion, chiefly with equites, whence the equites are called seminarium senatus. (Lamprid., 'Alex. Sev.', 19; Joseph., 'Antiq. Jud.', xix. 1.) Constantine established a second senate at Byzantium, and the emperor Julian conferred upon it the privileges which were enjoyed by the senators of Rome. (Zosimus, iii. 11.) Both senates were still sometimes addressed by the emperors in a imperial oration concerning matters of legislation, and each of the senates still continued to be a high court of justice, to which the emperors referred important criminal cases. The senatorial dignity was now obtained either by descent, by the favour of the emperor, or by virtue of having held some office at the imperial court. The senators enjoyed many distinctions, but their burdens were exceedingly heavy, for they had to pay a peculiar tax (follis) upon their landed property, to give public games, and magnificent presents to the emperors, and, in times of need, large donations to the people. The emperors, therefore, contrived to elect into the senate the wealthiest persons from all parts of the empire. (Walter, 'Gesch. d. Röm. Rechts.')

From the time of Diocletian the senate was only a shadow of its former state, but it was still the highest object of the ambition of the wealthy Romans.

It now remains to mention some of the external insignia and the privileges of the Roman senators.

1. The *latus clavus*, or *tunica laticlavia*, or a tunica with a broad purple stripe, which was not sewed to it, but woven in it.

2. A kind of short boots with the letter C on the top of the foot. This C is generally interpreted to mean centum, and to refer to the original number of a hundred (centum) senators.

3. A particular place (orchestra) in the theatres and amphitheatres.

This was first assigned to the senate by Scipio Africanus Major, B.C. 194 (Liv. xxxiv. 54; comp. Cic. 'pro Cluent.', 47.) In the reign of Claudius they obtained the same distinction at the games in the Circus. (Suet., 'Claud.', 21; Dion Cass., lx. 7.)

4. On the day when sacrifices were offered to Jupiter, the senators had a public feast on the Capitol, and this distinction, which no one else had, was called jus publice epulandi. (Suet., 'Aug.', 35; Gellius, xii. 8.)

5. The jus liberæ legationis, that is, senators, when allowed to travel abroad, had a right to demand from the inhabitants of the towns or countries through which they travelled, all that was necessary for their support or accommodation. Towards the end of the republic this right was much abused, wherefore Cicero obtained the passing a law which limited the time during which a senator might be absent and enjoy the jus liberæ legationis to one year: Cæsar, however, extended it to five.

SENECA INDIANS. [North American Indians.]

SENEGUIN. [Saponin.]

SENESCHAL, a word rarely used except by persons who affect a kind of refinement of style which they think is attained by using words of exotic growth rather than words the natural growth of their own soil, the meaning being precisely that which is represented by the word "steward," and this when the word is applied to officers so designated of the greatest eminence; the lord high-steward of England or of Scotland being the proper phrase for that great officer, and not lord-high-seneschal. But the functions of the officer called steward in Britain corresponding with those of the officer called seneschal abroad, and especially in France, when the word appears in Latin, it is represented by *senescallus*, writs running "Senescallo Hospitii Regis," &c., when addressed to the steward. In poetry and romance-writing it is sometimes used for a principal officer in the household of distinguished persons, when it is thought that the word steward would be too familiar, and suggest an officer whose duties are of an inferior class to those of the seneschal.

SENNA is prepared from several species of *Cassia* [Cassia, in Nat. Hist. Div.], of which the *acutifolia*, grown in Egypt, Sennaar, and Abyssinia, and shipped from Alexandria, is considered the best. The leaflets, leaf stalks, and pods are frequently present in the senna used in medicine. The pulp of *C. Fistula*, called also *Cathartocarpus Fistula*, consists chiefly of sugar and gum, with some other principles, and is a mild laxative. It accordingly enters into the composition of the confection of cassia, and the confection of senna or lenitive electuary. These are pleasant-tasted but rather bulky purgatives for children. They are not much used, and the pulp of cassia is chiefly employed to form what is termed essence of coffee. This, when prepared from pulp which has not been kept too long, is mildly cathartic, and a very proper article of diet for persons subject to habitual constipation.

Senna contains a peculiar principle called *cathartine*, with a fat oil, and a little volatile oil, a colouring principle, mucilage, and malate and tartrate of lime, chlorophylle, &c.

The active or purging principle is yielded to water, both cold and warm, and to alcohol. If the infusion be made with cold water, it never gripes: this method is now much employed to form the concentrated infusions supplied by wholesale chemists and druggists to country practitioners. It requires that the water should stand twenty-four hours on the leaves, which should be kept down with a heavy weight, and the air excluded as thoroughly as possible. The tincture is almost an unnecessary form, while the powder is objectionable from its bulk and disagreeable taste. Various articles, especially aromatics, are occasionally added to infusions to correct its griping tendencies, or increase its purgative power. The confection is an example of such combinations in a solid state. A carefully prepared extract keeps well, retains the odour and virtue for years, and may be given in moderate-sized boluses or pills.

SENSIBILITY, an aptitude for receiving impressions of the senses. This is its physiological meaning, as designating that faculty of the senses whereby things external are made to act upon us. That peculiar fineness of organisation which renders a man alive to the impressions of physical objects, has, by a natural metaphor, become the expression of that peculiarity of mental organisation which renders the mind alive to impressions of moral objects, such as pity for the distress of others, admiration of heroic courage or patient endurance, &c.; and thus a person with a keen sense of grandeur, sublimity, nobility, beauty, or pathos in nature or art, is said to possess great sensibility. It is this moral aspect of sensibility which in all people creates the love of poetry and fiction, and when possessed in a high degree creates the poet himself.

A singular but suggestive theory of universal sensibility was propounded by Campanella in his work 'De Sensu Rerum;' but its daring assumptions, however consonant to a poetical temperament, require greater accuracy, larger data, and more logical deductions, before this hypothesis can have any weight with exact thinkers; and in fact it has gained few converts.

SENTENCE. [Judgment; Organon.]

SENTINEL, or **SENTRY** (from *sentire*, to look or perceive), is a term now applied to an infantry soldier when placed on guard before the palace of a royal personage, or before some other public building; also when guarding the ramparts of a fortress, or, on an army being in the field, when he is stationed on the exterior of the line of outposts. [Piquet.]

SEPARATE PROPERTY. By the common law of England the husband acquired by the marriage a freehold interest in, and a right to dispose of, the rents and profits, during the joint lives of himself and his wife, of all the estates of inheritance of which she was at that time seised, or might become seised during the coverture, as well as a right to an estate for his own life as tenant by the curtesy in the event of his surviving his wife and there having been issue of the marriage. By the common law, also, marriage was an absolute gift to the husband of all the goods and personal chattels of which the wife was actually possessed at that time or might become possessed during the coverture, and it gave him a right to dispose of her chattels real and of such of her choses in action as he should have reduced into possession during the same period. There was no mode by which the wife could take or enjoy any estate or property absolutely independent of her husband.

In process of time, however, limitations of both real and personal property to the separate use of the wife were established in courts of equity, and the validity of them has been recognised even in courts of law. It was at first considered necessary that property which was to be enjoyed by a married woman for her separate use should be vested in trustees for her, but it has since been settled that where either real or personal property is given to the separate use of a married woman, without any appointment of trustees, the husband shall be considered a trustee for her. This principle applies *à fortiori* when the property is expressly given to the husband for the separate use of his wife. In the same manner the agreement in writing between the husband and wife before marriage, that his wife shall be entitled to any specific property for her separate use, converts him into a trustee for her as to that property; and if the subject of agreement be real estate, and be such as to give the wife a power of disposition, the agreement will be binding on her heir, and make him a trustee for her appointee. The consideration of what is or is not a valid settlement of property by the husband to the separate use of his wife as against creditors and purchasers, belongs to the general doctrine of marriage settlements. [Settlement.]

Many questions have arisen upon the construction of particular instruments as to what words are necessary to raise a trust for the separate use of the wife. The result of the cases upon this point may be stated to be, that when, from the nature of the transaction and the context of the instrument, the intention to limit the property to the wife for her separate use is clear, whatever may be the particular expressions used, that intention will be carried into effect; but that the courts of equity will not interfere to deprive the husband of the interest which he would otherwise take in his wife's property upon doubtful inferences or ambiguous expressions. It has sometimes been doubted whether property could be limited in trust for a woman, whether married or sole at the time, so as to enure to her separate use in the event of a second or future marriage; but the recent decisions upon this point, in accordance with the general practice of conveyancers, leave no room now to doubt their validity. The intention to extend the limitation to future covertures must, however, be clearly declared; for if the apparent object be to protect the fund against the particular husband, a declaration that the trust shall continue during the life of the woman will not extend it to a future marriage.

Separate estate may be acquired not only in lands and personalty, but in the profits of trade carried on by the wife on her separate account, in consequence either of express agreement between her and her husband before marriage, or his subsequent permission. Upon the general principles applicable to marriage settlements, the agreement in the former case will be good against creditors; in the latter against the husband only. In such cases the stock in trade and property required for carrying on the business are usually vested in trustees for the wife, who is considered at law as their agent, and should carry on all business transactions in their names. But if no trustees should have been appointed, the rule of equity before stated will apply, and the husband will be bound by his agreement, that all his wife's earnings in trade shall be her separate property and at her own disposal.

When personal property, whether in possession or reversion, is settled to the separate use of a married woman, she may dispose of it and the produce of it as a feme sole to the full extent of her interest, though no particular power be given by the instrument of settlement. But a mere limitation of real estate in fee to the sole and separate use of a married woman, though it enables the wife to dispose of the rents and profits as a feme sole, gives her no power of disposition over the estate beyond what she has by the common law. The gift to the separate use may be accompanied by an express power of appointment by deed or will. The rules of law relating to the formal execution of such powers, and the cases in which defective execution will be supplied, are the same as those which are applicable to the execution of powers in general. [Uses.]

It is not necessary in all cases of settlement of personal property to the separate use of a married woman, accompanied with a power of appointment, that she should appoint in terms of the power. Upon this point the following distinctions are established:—1. When there is an express limitation of an estate for life in the fund to the wife, with a power to appoint the principal after her death, the wife can dispose of the capital only by an execution of the power, which may be immediate, if the power authorise an appointment by deed; but if it require the appointment to be made by will only, then it cannot take effect till after her death. This is equally true whether the limitation in default of appointment be to a stranger, to the next of kin, or to the executors and administrators of the wife. 2. When the wife takes the absolute interest in the property, although it should be limited to her in the form of a power, she may dispose of it under her general power, and without regard to the ceremonies prescribed by the instrument. Under the second head are included all the cases in which the trust for the wife appears to be of the principal and not of the interest only, and the effect of such a limitation will not be controlled by the introduction of any subsequent provisions as to the mode of payment of the interest or otherwise.

The foregoing observations with respect to the powers of disposition by a married woman of the capital of a fund given generally to her separate use, are equally applicable to the cases where the interest or rent of property only, or income of whatever kind, is the subject of the settlement. If no particular power to dispose be given, she may do so under that general power which, as before mentioned, a married woman possesses over her separate personal estate, and even where a particular mode of disposition is prescribed in the instrument of settlement, she will not, it seems, be bound to follow it.

If the wife, having a general power of disposition of her separate property, permit her husband during his life to receive and apply her separate estate as his own, a gift from her will in general be presumed, and she will not be allowed at his death to charge his estate with the amount so received.

If the wife, having power to dispose absolutely of her separate property, die without making any disposition of it, the quality of separate property, it seems, ceases at her death, and the surviving husband is entitled to the fund. If the property consist either of chattels real or personal in possession, he will be entitled to them without administration; but if of choses in action, he must take out administration to her estate.

In some cases where a married woman, having an absolute power of appointment over a fund, has executed it, a bill has been filed, in order that the consent in court of the wife to the disposition might be taken; and this practice occasioned a doubt whether it was not necessary that the wife's consent in court should be obtained, especially in cases where the appointment was in favour of the husband. But unquestionably the appointment is valid without any such consent, and the presence of the wife in court, whether the appointment be to her husband or to strangers, is entirely unnecessary.

It was at one time doubted whether the wife's general power of alienation of her separate estate could be restrained by the expressed intention of the settlor, such restraint being thought repugnant to the interest which she had in the property; but the power of the settlor to impose it is now established by undoubted authority. The intention to impose this restraint will not however be inferred in the absence of express words to that effect. If the gift be to a woman unmarried at the time when it takes effect, a clause against anticipation, that is, a clause which prohibits or limits the power of alienation, though inserted expressly in contemplation of a future marriage, is inoperative, as it would be in the case of a man, to prevent alienation while she continues sole; and if the gift be to a woman married at the time, the property becomes absolutely disposable by her upon the expiration of the coverture. It has also been much questioned whether, in the cases supposed, the property, if not alienated by the woman while discovert, would be subject to the settlement to her separate use and to the prohibition against anticipation during any future coverture or covertures. The question has been decided in the affirmative, and is now well settled. (Tullet *v.* Armstrong, 4 M. & C., 390.)

It has been stated that if a married woman has property settled to her separate use, without any restraint on alienation, she may dispose of it as a feme sole, either with or without consideration; but it seems to be now determined (though there are conflicting decisions on the point among the older authorities), that, in order to affect her separate estate, she must show an intention to charge it, and that it is not liable to answer generally the demands of creditors. It is not very clearly determined in what cases and from what circumstances the intention to charge the separate estate will be presumed. It seems to be established that the separate estate of a married woman is liable to debts for which she has given a written security or acknowledgment, such as a bond or promissory note. The extent to which a woman's separate property may be subjected to the demands of creditors claiming under parol agreements has not been determined. If the separate property consists of land, it will of course not be liable; because, by the Statute of Frauds (29 Car. II., § 3), no agreements can affect lands unless they are in writing and signed by the party to be charged; but if of personalty, it is probable that an express parol agreement that her separate property should be charged with the payment of a debt, or even perhaps a tacit agreement to be implied from the circumstances, as when the wife is living separate from her husband, would be held binding on the property.

It has sometimes been considered that upon the principle of the general liability of the separate property to debts, after the death of the wife, in the administration of it among creditors, all ought to come in *pari passu*, as in other cases of the administration of equitable assets; but the later authorities seem to show that the separate property of a feme covert is not subject at her death to any such general liability, and from this it would appear to follow that the creditors whose debts are charged upon it ought, as specific incumbrancers, to be paid according to their priorities.

The wife, in equity, as at law, can incur no personal responsibility by her engagements as to her separate property, and is liable only to the extent of that property in the hands of her trustees; but in suits respecting her separate estate she is treated in all respects as a feme sole, and is personally answerable for contempt in not obeying the orders of the court. In such suits, if she is a plaintiff, she must sue by her next friend, and not with her husband, who however should be made a defendant to the wife's bill: and if she is a defendant, she must be served personally with process in the cause. She must answer by her next friend separately from her husband, who ought however to be made a party to the bill.

The savings and earnings of a wife may become her separate property *at law*, and she may deal therewith as a feme sole, either where an order has been made to that effect under the statute 20 & 21 Vict. c. 85, or a judicial separation has been obtained by the wife.

(Bright, *On Husband and Wife;* and Lord St. Leonards, *On Powers.*)

SEPARATION A MENSA ET THORO. [DIVORCE.]

SEPARATION, JUDICIAL. Until the statute 20 & 21 Vict. c. 85, divorces *a vinculo*, which put an end to the marriage altogether, were only obtainable by a special act of parliament, which the legislature would not pass in favour of a husband until after a sentence of separation *a mensâ et thoro* in the ecclesiastical court, and would not pass at all if his conduct had not been free from reproach. [DIVORCE.] Either of the spouses could always however obtain, on the ground of adultery, cruelty, and certain other causes, a divorce *a mensâ et thoro*.

The remedy now given in such cases by the Court for Divorce and Matrimonial Causes is termed a *judicial separation*. This, like a divorce *a mensâ et thoro*, does not dissolve the marriage; it does not bar the wife of her dower, for instance; it effects only such a separation of the parties as leaves it open to them to come together again. But it relieves the husband from all liability for his wife; and it confers on the wife the right of having and disposing of her own property and earnings, as freely as if she were a feme sole.

This kind of separation may be obtained on the ground of adultery or cruelty, or desertion without cause for two years or upwards; but unlike a decree for a divorce, which is absolute and irreversible, a sentence of judicial separation may be reversed at any time afterwards, if obtained in the absence of the defendant, on its appearing that there was reasonable ground for the alleged desertion.

In cases either of divorce or judicial separation, the Court may, if it shall think fit, order that the husband shall secure to the wife such sum as it shall deem reasonable. The allowance which may thus be made to a woman for her support out of the husband's estate, is to be settled at the discretion of the court on consideration of all the circumstances of the case, and to be proportioned to the rank of the parties.

SEPIRINE. A resinous alkaloid, found along with *bebirine* in the bark of the *bebeeru* tree of British Guiana.

SEPOY, or SIPOY, the name of the native soldier in the East Indies, probably from *sipahi*, the Persian word for soldier, though Bishop Heber derives the word from "sip," the bow and arrow, which were originally in almost universal use by the native soldiers of India in offensive warfare. Those Bhiels and Kholees who are employed in Guzerat in the service of the police and in protecting gentlemen's houses and gardens are also called sepoys, and with more propriety, as they still use the bow and arrow. The native soldiers in the pay of the British government now form a large army, well trained in European discipline. Though the men of some of the regiments composed of men of the highest caste are said to have been of a greater average size than the Europeans, the generality are somewhat smaller than European soldiers, but brave, hardy, and active, capable of undergoing much fatigue and of sustaining great privations. To the attachment and bravery of this army, which was not doubted till rudely shaken by the mutiny of the Bengal army in 1857, Great Britain is chiefly indebted for the possession of her Indian empire, and the security of her sovereignty over a territory vastly more extensive than her own, and separated from her by the distance of nearly half the globe.

Bombay was the first possession which the English obtained in India, but the establishment on that island was for a long time on a very limited scale, and required nothing more than its own garrison and a few companies of native troops, who were peons, subject to little control, to no fixed military law, and who used their native weapons in preference to muskets. The French were the first to set the example of employing natives regularly instructed in European discipline. Labourdonnais, in the siege of Madras in 1746, had 400 sepoys well armed and well trained, besides 400 disciplined negroes from Madagascar, in addition to his European soldiers. A corps of 100 sepoys from Bombay and 400 from Tellichery are mentioned as having joined the army of Madras in 1747, but these were probably only peons and bands of undisciplined natives hired for the occasion. In 1748 a small corps of natives was raised in the neighbourhood of Madras, and trained and disciplined by Mr. Haliburton, a lieutenant. From 1748 to 1766 the sepoys were in separate companies of 100 each, commanded by subadars, or native captains, though under the superintendence of Europeans. In 1766 the companies were formed into battalions of 1000 men each, commanded by European officers, under whom the subadars still retained their rank and influence. In 1796 two battalions were made to constitute a regiment, which continued to be the form till about 1820, since which time each regiment has been made to consist of two battalions of 500 men each. This description of force was adopted also in Bombay and Madras, and continued to increase. In 1856, just before the mutiny of the Bengal army, the native army was composed of 240,120 men, forming,—

5 Troops of horse artillery.
18 Companies of artillery.
22 Regiments of regular cavalry.
155 Regiments of regular infantry.
23 Regiments of irregular cavalry.
30 Regiments of irregular infantry.
5 Contingent brigades of all arms.
1 Native legion.

The native army, which, with the whole of the Company's troops, were in 1858 transferred with the government of India and placed under the crown, having been in great part destroyed by the mutiny of the Bengal army, is now greatly reduced, and is being reorganised and placed on the footing of irregulars. In irregular regiments the number of European officers is very small, the men receive high pay, and provide their own horses, forage, &c.

SEPTEMBER, the ninth month, as the year is now divided by European nations. It consists of 30 days. Etymologically the name is improper, being a Latin term formed of *septem*, seven, and the termination *ber*; and the same impropriety belongs to October, November, and December. The Roman year originally commenced in March; and the English names of the months, which are all Latin terms, appear to have been given to them by the lawyers, whose writings were formerly in Latin, and who supposed the year to commence in March, on which supposition the names are right, September being the seventh, October the eighth, &c., when March is the first. The legal year in England was not made to commence on the 1st of January till the alteration of the style in 1752.

Other appellations were given to this month under some of the Roman emperors. The Saxons called it *Gerstmonath*, or barley-month, gerst being the original Saxon name for barley, which was the chief grain cultivated by the Saxons, and commonly harvested in this month.

SEPTUAGESIMA. [Sexagesima.]

SEPTUAGINT, or THE ALEXANDRINE VERSION OF THE OLD TESTAMENT, the most ancient translation of any part of the Scriptures. It is in the Greek language. The account of its origin is given in a letter ascribed to Aristeas, an officer at the court of Ptolemy Philadelphus, and repeated by Josephus ('Antiq.,' xii., c. 2) and Eusebius 'Præpar.', Evang. viii., c. 2–5. [Aristeas, in Biog. Div.]

Philo says that the Septuagint was translated from the Chaldaic, by which he means the Hebrew Scriptures as they existed after the Captivity. But from certain points of resemblance between the Septuagint and the Samaritan Pentateuch, many eminent critics have concluded that the former was translated from the latter, and not from the Hebrew. It is, however, quite incredible that, if this had been the case, the Septuagint should have been, as it was, universally received by the Jews.

The character of the version varies greatly. By far the best part is the version of the Pentateuch, which was evidently made by a man well acquainted with both Hebrew and Greek. Next in value is the book of Proverbs, which is for the most part very accurate, and displays much poetical taste. The translation of Ecclesiastes is too literal. The books of Judges, Ruth, Samuel, and Kings appear to have been translated by the same author, and do not contain so many Hebraisms as other parts of the version. In the book of Job many interpolations are made in the narrative, and there are considerable omissions in the poetical parts. The book of Esther, and the Psalms and Prophets, appear to have been translated between 180 and 170 B.C., but in a very inferior manner: indeed a great part of the version of the Psalms is quite unintelligible. Jeremiah is the best translated of the prophets; next come Amos and Ezekiel. The version of Isaiah, which Lowth places 100 years later than that of the Pentateuch, is the worst of all, except that of Daniel, which differs so much from the Hebrew, that the early Christians rejected it altogether, and substituted the version by Theodotion in its place. The Septuagint contains also the apocryphal books of the Old Testament. [Apocrypha.]

The Septuagint was used not only by the Hellenistic Jews, but by all Jews who understood Greek; and even some of the Talmudists mention it with praise. It is constantly quoted by Josephus, and very frequently by the writers of the New Testament.

Soon after the Christian era, however, we find the opinion of the Jews respecting it very much altered, probably in consequence of the use made of it against them by the Christians. They went so far as to institute a solemn feast on the 8th of the month Thebet (December) to execrate the memory of its having been made, and afterwards a new version, that of Aquila, was made for the express purpose of superseding the use of the Septuagint in the synagogues. [Aquila, in Biog. Div.] The fathers of the Greek church always quote the Septuagint. All the early versions, except the Syriac, were made from it. And thus, through the Vulgate, it was used in the Latin as well as in the Greek church. Its text having become corrupted by frequent transcription, Origen undertook to revise it, and produced his celebrated 'Hexapla.' [Origenes, in Biog. Div.]

At the end of the 3rd and the beginning of the 4th centuries, three recensions of the text of the Septuagint were produced. The first was undertaken by Lucian, a presbyter of Antioch, who suffered martyrdom A.D. 311. This edition was conformed to the Hebrew text, and was received in the churches from Antioch to Constantinople. The second was edited at the same time by Hesychius, an Egyptian bishop. It is not known whether he followed the Hebrew text or ancient manuscripts of the Septuagint; but his alterations appear to have been fewer than those of Lucian. His edition was received by the churches of Egypt, and is cited by Jerome as the 'Exemplar Alexandrinum.' The third was transcribed by Eusebius and Pamphilus from the text in the Hexapla, with the whole of Origen's critical marks. In process of time these marks became so altered by frequent transcription, that they were at length altogether omitted, so that it is now impossible to distinguish Origen's emendations from the original text. This edition was received by the churches of Palestine, and had a place in all libraries. All the subsequent editions of the Septuagint are founded upon these three recensions.

There have been many modern editions of the Septuagint; the earliest is the Complutensian in 1514–1517.

For an account of the other Greek versions of the Old Testament, see Aquila; Symmachus; Theodotion, in Biog. Div. (The 'Introductions' of Horne and Jahn, and the authorities quoted by them.)

SEQUESTRATION. [Benefice.]

SEQUESTRATION is a process by which the revenues of an ecclesiastical benefice are received and applied by persons other than the incumbent of it. It issues immediately from the bishop in all cases, but it may be founded upon proceedings commenced either in his own court or in the temporal courts. It is a mandate, in the nature of a warrant, addressed by the bishop to the parties who are to execute it. These are called sequestrators, and in general are the churchwardens of the parish. So far as regards their duties under the sequestration, they are a kind of bailiffs. They collect the fruits of the benefice, and apply them according to the directions they receive in each case.

The occasions on which a sequestration is founded on proceedings in the court of the bishop are various. There may be a sequestration where a living is vacant by death; in order to provide for the expenses of supplying the cure, and to preserve the surplus for the successor. Where the title to a living is in dispute, a sequestration may issue under which some third party collects the fruits, and, after defraying the salary of the curate and other necessary expenses of the benefice, retains the surplus for the party who may appear to be lawfully entitled. There are many occasions also where the bishop acting judicially may sequester a living, as where the parsonage-house is in decay, and the incumbent, after due admonition, which may be made by the archdeacon, fails for a period of two months to repair it. The payment of a curate's salary may also be enforced by sequestration.

Sequestrations founded on proceedings in the temporal courts occur under the following circumstances:—The sheriff, the ordinary ministerial officer of those courts, has no power to interfere with ecclesiastical revenues. When a judgment therefore has been obtained against a beneficed clergyman, and execution has issued upon it, and the clergyman has no lay property upon which the sheriff can levy, he makes a return that the defendant is a beneficed clerk having no lay fee within his bailiwick. The plaintiff may then sue out a writ addressed to the bishop, directing him to levy the amount upon the clergyman's ecclesiastical goods. The bishop upon this issues a sequestration, directing the sequestrators to levy the debt upon the profits of the benefice; or the plaintiff may sue out a sequestrari facias, addressed to the bishop. The bishop, under these circumstances, is said to be a kind of ecclesiastical sheriff; and the temporal courts, in so far as relates to his duties as such ministerial officer, have the same power over him as they have over the sheriff, and his duties are analogous. [Sheriff.] The sequestration ought to be forthwith published by reading it in church during divine service, and afterwards at the church-door. The party obtaining it may, on giving proper security, name his own sequestrators. Under either of those writs the plaintiff is entitled to the growing profits, until the whole sum endorsed upon it is satisfied, even although this should not occur till after the time at which the writ is returnable. The necessary expenses of the sequestration, &c., are also leviable under the writ. The lands are bound from the time of the delivery of it to the bishop.

Sequestration in chancery is a "writ issuing out of the court, directed to four or more commissioners, empowering them to enter into a defendant's real estates, and to sequester into their own hands not only the rents thereof, but also all his goods, chattels, and personal estate whatsoever, to keep the same until the defendant has fully answered his contempt." It issues upon the occasion of their committing a contempt against the court, by keeping out of the way of the serjeant-at-arms, or escaping from custody, or disobeying an order of the court to pay money.

Sequestration also may be issued from the Courts of Common Law against a corporation, to compel obedience to a mandamus or injunction.

SEQUESTRATION (Scotland). [BANKRUPT LAWS OF SCOTLAND.]

SEQUIN. [MONEY.]

SERA'GLIO, properly *serai*, the palace of the Sultan of Turkey; in this sense the word is also applied to the houses of foreign ambassadors resident at his court. The seraï of Constantinople stands in a beautiful situation, on a head of land projecting into the sea, formerly called Chrysoceras, or the Horn of Gold, now Seraglio Point. The walls embrace a circuit of about three miles. Its outward appearance is not imposing, though its extent is large. The principal entrance, a large pavilion, which looks more like a guard-house than the entrance to a palace, is always guarded by *capidjis*, officers of the seraglio; but this is the Porte, from which the title of the Sublime Porte has arisen. That part of the building which is occupied by the women of the sultan has been improperly called *seraglio*, and hence the word has become synonymous with *harem*, an Arabic word, meaning "sacred spot," or that part of the house where the women and daughters of the Mohammedans reside.

SERAI, a large building for the accommodation of travellers, common in Eastern countries. The word is Persian, and means in that language, "a palace, the king's court, a large edifice;" hence *karávánserai*, by corruption *caravansarie*, that is, place of rest for caravans. In Turkey these buildings are generally called *khans*, from *khán*, another Persian word, which has a similar meaning. In Tartary and India they are simply called *serais*. The erection of these buildings is considered highly meritorious by Hindus as well as Mohammedans, who frequently endow them with rents for their support. [SERAGLIO.]

SERALBUMEN. [OVALBUMEN.]

SERAPEUM, the name given to two celebrated Egyptian temples, one at Alexandria, the other at Memphis, dedicated to the god Serapis. There was also a temple of the same name at Babylon, where the friends of Alexander the Great wished to transport him during his last illness (Arrian, 'Anab.,' vii. 56.) The temple of Serapis at Alexandria was preceded by an older one dedicated at Rhacotis. (Jul. Valer., 'Alex. Ort.,' I. xxxi.) All these temples derived their name from the god Serapis, who was affirmed by Manetho to be Pluto, or the Jupiter of Sinope. (Plutarch, 'Isid and Osirid,' xxxvii.) Of the many etymologies proposed for the name of the god, that of St. Clement of Alexandria is now recognised to be the correct one, Serapis being composed of two words signifying the Osiris, or deceased Apis, from the name of Osiris having been applied to all mortals after death, and to the bull considered as a demigod. Recent discoveries at Memphis have shown that the Serapeum was the cemetery of the Apis, and close to the Apeum where the bull dwelt during his life. The Apeum was established here after the time of the Psammetichi, where it still existed in the days of Herodotus (ii. 21). But the Serapeum or mortuary temple of the Apis was founded by Shaemgam, the son of Rameses II., who removed thither the tomb of the sacred bull. This temple was discovered by M. Mariette, at the west end of a dromos of sphinxes lying to the north of the Pyramids of Sakkara. It seems to have been enlarged and repaired till the days of Neththerhebi or Nectanebes I., of the 30th dynasty. Another temple, lying on the east end of the same dromos, seems to have been that erected in Ptolemaic times, and continued to be used for the Apis and the worship of Serapis till the days of the Emperor Julian, and even later. This Serapeum at Memphis was called the Great, to distinguish it from that of Alexandria, which was surnamed "the most illustrious." It comprised, or was a portion of, a group of buildings, consisting of the Astarteum, dedicated to Astarte; the Anubeum, to Anubis; the Asclepeum, or Temple of Æsculapius, in which libations were daily offered; the dwellings of the hierarchy; and the apartments or hospital of the sick who flocked to the temple for the sake of the cure of their maladies, which was supposed to be effected through the dreams accorded by the god during their sleep in the sacred edifice. One hundred and forty-six papyri discovered in the adjacent ruins, and now dispersed through the museums of Europe, relating to the quarrels and litigations of the functionaries of the temple, have thrown great light on its administration. They all date from the 18th to the 24th year of Ptolemy Philometor, and describe the temple as connected by a dromos of sphinxes with the city of Memphis, and which had not then, as in the days of Strabo, been buried in the sand. (Strabo, xvii. 807, c.) The temple was under the direction of prefects, delegates, vicars, subadministrators, and storekeepers, and two female priestesses called Didymi, or "twins," whose office was to serve Æsculapius and Serapis, and a peculiar class of hierodules, who voluntarily dedicated themselves to the service of the gods, and lived in celibacy and seclusion within the precincts. These persons derived no support from the revenues of the temple, and were either maintained by their families or the alms of visitors to the sacred edifice. They had in their hands the charge of affairs, but could not go beyond the precincts, and lived to all intents a cloistered or monastic life. This institution is mentioned as late as Antoninus Pius, and is evidently that from which monachism has been borrowed. (Peyron, B., 'Papiri Greci,' p. 14.) There were also many officers attached to the worship of the Apis, who had two shrines, into which he entered at pleasure, and from which passage augury was taken by the priests. The sacred bull was attended by a herdsman while living, and an entaphiastes or embalmer when dead. (Peyron, B., 'Papiri Greci,' p. 8.) His mother also participated in his honours, and had a shrine assigned her in the Apeum. Extraordinary care and vast sums were expended both by native and Greek monarchs in embellishing these shrines; and if the old capital of Memphis was comparatively neglected during the sway of the great Theban dynasties, this was amply compensated by the magnificent donations of the later Saitic dynasty and the Ptolemies. Apis is mentioned on monuments of the 4th dynasty, and his shrine must have been established as early as the building of the oldest Pyramids.

The remains of this edifice were discovered in the plains of Sakkara, in 1850 by M. Mariette, then an employé of the Louvre, who had been sent to Egypt to collect Coptic manuscripts for the French government, where he first found the dromos of sphinxes connecting the temples. This excavation was a work of great labour, the dromos having been made through the ancient cemetery of Sakkara, and curved to avoid injuring the tombs, and partly buried under a great depth of sand; after excavating a length of 7000 feet and uncovering 141 sphinxes, he discovered at the end of the avenue a semicircle ornamented with statues of the sages, poets, and philosophers of ancient Greece, supposed to have formed part of the library of the Serapeum. Between this semicircle and the two last sphinxes he found a transverse avenue, the right branch of which led to a temple erected to Apis by the monarch Nectanebes, or Neththerhebi; the left branch, paved with large stones, led to the Serapeum itself. The dromos was about 860 feet in length, flanked on each side by a low wall, divided on the left side about the middle by a small Greek building having before it a nos in which was a statue of Apis, probably that described by Strabo. On each side of the temple and on the wall, were allegorical figures of boys riding on chimeras and animals, and at the end of the dromos were the pylons or gateways of the Serapeum.

The wall, built in the reign of Neththerhebi, was covered with sepulchral altars, and 428 small bronze votive figures of deities were discovered in a niche. At this stage, owing to difficulties with the Egyptian government, the excavations were stopped in 1851, and not resumed till the spring of 1852. In November of 1851, the first tombs of the Apis were discovered, 640 sepulchral tablets, five entrances, and various small objects. This great subterraneous cemetery divided itself into two parts, the first of which had its entrance at the south end, and went in a northern direction forming a vaulted gallery like a tunnel, having at its side about 20 chambers, the oldest of the age of Rameses II., and the most recent of that of Psammetichus I. During this period the remains of 24 Apis mummies showed that this number of generations of cattle had lived and died during that chronological period. The other part of the cemetery was a souterrain divided into a considerable number of galleries, commenced in the 52nd year of Psammetichus I., and continued till the commencement of the Roman Empire. The bull mummies of this division were deposited in gigantic monolith sarcophagi of Syenitic granite, transported from the quarries above the first cataract. These sarcophagi ranged from 11 to 12 feet high, 14 to 15 feet long, and weighed 6500 kilogrammes; or above 64 tons, 24 of them were found in the 40 chambers of this tunnel. The tablets were not fixed to the inner walls but to the lintels of the doors, and were chiefly inscribed in demotic characters, and the most important one was placed in the midst of the wall which closed the door of the chamber, containing the dates of the birth, enthronement, death, and burial of the Apis. Only four of these sarcophagi had inscriptions, one bore the date of the 2nd year of Khabash, a Persian king, supposed to be later than Darius; another that of the reign of Cambyses; a third in that of Amasis II.; and the last that of Ptolemy. The result of these researches showed that the bull, said to have been stabbed by Cambyses, survived till the reign of Darius. Among the mummies of the Apis were found two others of men, evidently of the highest rank, who had been buried with the sacred bulls. The bulls which died from the commencement of the reign of Amenophis III. to the middle of that of Rameses II., had a mortuary chapel with four columns erected above the tomb, which was a chamber with a flat roof hollowed in the solid rock below, and the votive tablets of the adorers of the deceased bull were built into the stylobate of the mortuary chapel. The bull was treated as a deceased human being, and the sarcophagi were accompanied by sepulchral vases, and the visitors to the tomb deposited the usual sepulchral figures offered to the dead; but at the later period of the age of Rameses the tombs consisted of chambers on each side of the gallery, with the votive tablets placed in the gallery; and the sepulchral figures, deposited in the cases, were strewn along the floor, or inserted into niches in the wall. After the 53rd year of Psammetichus II., the chambers became more magnificent, being above 30 feet high, with vaulted roofs of white limestone, and the walls faced with stone from the Tourah quarries; the sarcophagi were of the finest red Syenite. At the period of the 30th dynasty the tablets were not allowed to be placed inside the tomb, but were restricted to the entrance, and the walls of the roads conducting to the tomb. After the epoch of Darius, the tombs are far less magnificent. The Apis of Cambyses is deposited in the vestibule of that which died in the 4th year of Darius. All the sacred bulls were not buried with the same honours, those most carefully embalmed having their principal bones placed in a wooden coffin inside the granite sarcophagus; others were cast into a hollowed place in the rocky pavement, and covered with a mere flagstone. The tablets found consisted chiefly of hieroglyphical inscriptions intermixed with demotic, commencing with the 15th year of Darius, and consisted of two classes: the sepulchral, or tombstones of the bull, on which was inscribed the date of the death of the sacred bull, that of his birth, and of his installation at Memphis, and the age which he had reached; and votive tablets dedicated by individuals to the departed Apis for the usual benefits supposed to be accorded by the gods. About 1200 of these tablets were found, and they have thrown great light upon the chronological period and succession of the monarchs of the 21st and 22nd dynasty. Altogether, 7000 objects were found, 3000 of which referred to the worship of Apis, a number by no means remarkable when it is considered that Ptolemy I. spent about 10,000*l.* on the funeral of an Apis. The sepulchres were of bulls which died in the following reigns—Amenophis III., Amenankhut, Horus, and Khuenaten, of the 18th dynasty; of Sethos I. and Rameses II., three of which happened in the 16th, 26th, and 30th years of the last-named monarch, of the 19th dynasty; of Rameses III., V., VIII., XIV., of the 20th dynasty; of Osorchon II., Takelothis I., Sheshonk III., IV., of the 22nd dynasty; of Boochoris, of the 24th dynasty; of Sabaco and Tirhaka, of the 25th dynasty; of Psammetichus I., II., and Aahmes, of the 26th dynasty; of Cambyses, Darius, and Khabash or Smerdis, of the 27th dynasty; of Neththerhebi, of the 30th dynasty. The tablets subsequent to this reign, chiefly demotic, consist of votive inscriptions in honour of Apis, and they gave the following dates for the appearance of the Apis: B.C. 258, in the 32nd year of Ptolemy Philadelphus; B.C. 231, the 20th year of Euergetes; B.C. 210, the 14th year of Ptolemy Philopator; B.C. 185 and 165, in the reign of Ptolemy Philometor; B.C. 142, the 13th year of Ptolemy Euergetes II.; and B.C. 117, in the reign of Ptolemy Euergetes II. The temple of Æsculapius was also partially uncovered by M. Mariette, but tradition had assigned the spot to be the prison of Joseph, and the work could not be carried on.

(Mariette, Aug. *Choix de Monuments decouverts pendant le déplacement du Serapeum de Memphis*, 4to, Paris, 1856; *Memoire sur la mère d'Apis*, 4to, Paris, 1856; *L'Athenæum Français*, 1855, 1856.)

SERAPHINE, a musical instrument of the keyed kind. It may be described as a small organ, in which short, thin, and narrow steel bars, or springs, put into vibratory motion by means of a bellows acted on by the foot, are used instead of pipes. It was one of the predecessors of the HARMONIUM, which now takes the place of such instruments as are not portable. The portable forms are represented by the CONCERTINA. See also ACCORDION.

SERAPIS. [SERAPEUM.]

SERENADE, a word adopted from the French *sérénade*, which is derived from the Italian and Spanish *serenata*, a term formed from the Latin *serenus*, clear, serene. A serenade is properly music performed in the open air on a serene night, but is generally restricted to a musical performance given at night by a lover to his mistress under her window. The giving of serenades is little practised except by the Spanish and Italians, who generally on these occasions use the guitar as an accompaniment to their songs.

SERIES. The mathematical meaning of the word series is, a set of terms, finite or infinite in number, connected together by addition or subtraction, and formed upon some distinct law. If it had been the plan of this work to write treatises on the various branches of pure mathematics, the present article would have been brief, and abounding in references to the articles on algebra and the differential calculus, the most important results of which are expressed in series; but in a work which, without entering into such full details, professes to furnish references to the most important detached doctrines of the exact sciences, the present article must extend to some length.

Series may be either finite or infinite in the number of their terms. As to finite series, such for instance as 'x terms of $1+2+3+\ldots.$,' the only question of importance which generally arises with respect to them is, how to express the sum as a function of the indefinite number of terms, x. On this point we refer to the articles INTEGRATION, FINITE, and SUMMATION: it is with the doctrine of infinite series that the mathematician is more particularly concerned in the present article. Again, as to the manner in which the differential calculus is applied to the development of functions in series, we refer to TAYLOR'S THEOREM.

A series of an infinite number of terms may be either purely numerical, as $1+2+3+4+\ldots\ldots$, in which the symbol $+\ldots$, or $+$, &c., means that the series is to be carried on for ever, the law of formation of the written terms being continued through all the unwritten ones; or it may contain literal expressions with an obvious law of formation, as in $1+2x+3x^2+\ldots.$ A series of the latter class is reduced to one of the former so soon as any definite value is given to the letters it contains.

An infinite series may be either convergent or divergent, as explained in the article CONVERGENT. The various tests there explained will perhaps serve to settle this point as to the greater number of series actually employed; but the following ('Diff. Calc.,' 'Lib. of Useful Knowl.,' pp. 236, 326; we shall refer to this work in the sequel under the letters D. C.) will leave no doubtful case, though its application may sometimes be troublesome.

Let ψx be the xth term of a series $\psi 1+\psi 2+\psi 3+\ldots.$ (thus a^{x-1} is the xth term of $1+a+a^2+\ldots.$; $x a^{x-1}$ of $1+2a+3a^2+\ldots.$), and let $\mathrm{P}_0=-x\psi' x:\psi x$, $\psi' x$ being the differential coefficient of ψx. Let a_0 be the limit of P_0 when x increases without limit; then if a_0 be greater than 1, the series is convergent; if a_0 be less than 1 (negative quantity included), divergent; if $=1$, doubtful.

In the doubtful case of the preceding, let $\mathrm{P}_1=\log x\,(\mathrm{P}_0-1)$, and let a_1 be its limit when x increases without limit. Then if a_1 be >1, the series is convergent; if <1, divergent; if $=1$, doubtful. In this doubtful case examine $\mathrm{P}_2=\log\log x\,(\mathrm{P}_1-1)$, of which let the limit be a_2. Then if $a_2>1$, the series is convergent; if <1, divergent; if $=1$, doubtful; and so on. In brief, take the set of quantities

$$\mathrm{P}_0=-x\,\frac{\psi' x}{\psi x},\ \ \mathrm{P}_1=\log x\,(\mathrm{P}_0-1),\ \ \mathrm{P}_2=\log\log x\,(\mathrm{P}_1-1),$$
$$\mathrm{P}_3=\log\log\log x\,(\mathrm{P}_2-1),\ \text{\&c. \&c.};$$

make x infinite; then, according as the first of these which differs from unity is greater than or less than unity, the series is convergent or divergent. If it be more convenient to write $1:\phi x$, instead of ψx for the xth term of the series, then P_0 must be $x\phi' x:\phi x$, instead of $-x\psi' x:\psi x$. Nor need ψx be the xth term; it may stand for the $(x+n)$th term, n being constant.

By the symbol $\mathrm{s}\phi x$ is here meant the series $\phi x+\phi(x+1)+\phi(x+2)+\ldots.$; but when a number is written beneath s, as in s_2, it indicates the value of x in the first term of the series. Thus $\mathrm{s}_4 x$ stands for $4+5+6+\ldots.$, $\mathrm{s}_a\log x$ stands for $\log a+\log(a+1)+\ldots.$ Some such abbreviation is most wanted in an article of reference, in which compression is desirable; but the student should write his series at more length until he is well accustomed to them.

A divergent series is, arithmetically speaking, infinite; that is, the quantity acquired by summing its terms may be made greater than any quantity agreed on at the beginning of the process. Such is evidently the case with $1+2+4+\ldots.$, or $\mathrm{s}_0 2^x$. Nevertheless, as every algebraist knows, such series have been frequently used as the *representatives of finite quantities*. It was usual to admit such series without hesitation; but of late years many of the continental mathematicians have declared against divergent series altogether, and have asserted instances in which the use of them leads to false results. Those of a contrary opinion have replied to the instances, and have argued from general principles in favour of retaining divergent series. Our own opinion is, that the instances have arisen from a misunderstanding or misuse of the series employed, though sufficient to show that divergent series should be very carefully handled; but that, on the other hand, no perfectly general and indisputable right to the use of these series has been established *à priori*. They appear always to lead to true results when properly used, but no demonstration has been given that they must always do so.

Before, however, we proceed to reason upon them, we must distinctly understand what we mean by an *infinite* series. Some persons cannot imagine an infinite series, except by means of successions of finite terms: thus they have no other idea of $1+2+4+8+\ldots$, except as something of which the conception is a pure result of the successive consideration of 1, $1+2$, $1+2+4$, $1+2+4+8$, &c. If they can get no further than this, that is, if at no stage of their contemplation can they treat $1+2+4+\ldots$ as anything more than carried to some enormous number of terms, with a right to carry it further; we can then concede to them the right to object, in the manner described, to the use of a divergent series, though we think it possible that even in this case an answer might be given to the objection. But if there be any who can with us carry their notions further, and treat the series as *absolutely endless*, in the same manner as we are obliged to conceive time and space to be absolutely endless, looking upon the result not as to its arithmetical value, but as to its algebraical form and capability of being the object of algebraical operations—we then think that we have those with whom the question of divergent series can be argued on something more like a basis of demonstration. They may arrive at the final idea by means of the successions which the first class of thinkers say *must end somewhere*; but they answer, that this is no more true than that space must end somewhere: if it be granted that we are capable of conceiving a straight line extended without limit, with equal parts set off throughout its total infinite length, it must equally be granted that we might suppose one term of a series written at each and every point of subdivision. To this issue the question might be brought, namely, the alternative of allowing the conception of the infinite series, or of denying that of the infinite straight line. And it must be remarked that the considerations by which we limited the use of the word INFINITE in that article do not apply here, for we are not reasoning upon any supposed * attainment of the other end of the straight line, but upon ideas derived from a process of successions carried on during such attempt as we can make in our thoughts towards that attainment.

This being premised, let us now consider the series $1+a+a^2+a^3+\ldots$

---

* Indeed it is only a phraseological attainment of infinite magnitude which is used in the article cited: when we *say* that $a=b$ if x be infinite, we mean that a and b never cease to approach each other so long as the value of x increases.

ad infinitum, the last words being used strictly in the above sense, without reference to any particular value of a, and only as an object of algebraical operation. To what finite function of a is this an algebraical equivalent in all matters of operation? Let us consider first merely results of operation, without any question as to whether the series operated on have values or not, or whether expressions which appear to be the same so far as operations are concerned, are to be the same in value or not, when any difficulty arises as to the value of either. We assume those five rules of operation and their consequences, on which [OPERATION] the technical part of algebra is founded. If we then call the preceding series P, we find that P and $1+a\,\mathrm{P}$ are the same series. If then $\mathrm{P}=1+a\,\mathrm{P}$, we find $\mathrm{P}=1:(1-a)$, a result which is certainly not true in any arithmetical point of view, when $a>1$; for in such a case the series is infinite, and the finite expression negative. Leaving this, let us assume, for trial if the reader pleases, the equation $1:(1-a)=\mathrm{s}_0 a^x$; in this change a into $1:a$, and add, which gives

$$\frac{1}{1-a}+\frac{a}{a-1}=2+\mathrm{s}_1 a^x+1+\mathrm{s}_1 a^{-x}$$

or $1+\mathrm{s}_1(a^x+a^{-x})=0$, a result which is again perfectly incongruous in an arithmetical point of view. At full length it is

$$1+a+\frac{1}{a}+a^2+\frac{1}{a^2}+\ldots\ldots=0.$$

To test this curious result, by operations merely, call it ϕa, and multiply $\mathrm{A}+\mathrm{B}a+\mathrm{C}a^2+\ldots\ldots$ by it: the result, by common rules, will be found to be

$$(\mathrm{A}+\mathrm{B}+\mathrm{C}+\ldots\ldots)\,\phi a=(\mathrm{A}+\mathrm{B}a+\ldots\ldots)\,\phi a;$$

a result which agrees perfectly with $\phi a=0$, and with no other supposition whatsoever.

A great many other instances might be given, in which the use of $\phi a=0$ makes sense, so to speak, of results in the formation of which ϕa has been used. And it is generally admitted that divergent series are found to make sense, in the same manner, of almost every result in the formation of which they are used; and also that when such results happen themselves to be free of divergency, there is very rarely any distinction, as to either truth or clearness, between them and the results of ordinary algebra; insomuch that the objection of those who would avoid them altogether, as usually stated, amounts, so far as operations are concerned, to the assertion that they *sometimes* give false results.

If we then compare the position in which we stand with respect to divergent series, with that in which we stood a few years ago with respect to impossible quantities, we shall find a perfect similarity. The divergent series, that is, the equality between it and a finite expression, is perfectly incomprehensible in an arithmetical point of view; and so was the impossible quantity. The use of divergent series has been admitted, by one on one explanation, and by another on another, almost ever since the commencement of modern algebra; and so it was with the impossible quantity. It became notorious that such use generally led to true results, with now and then an apparent exception, which most frequently ceased to be such on further consideration; this is well known to have happened with impossible quantities. In both cases these apparent exceptions led some to deny the validity of the method which gave rise to them, while all were obliged to place them both among those parts of mathematics (once more extensive than now) in which the power of producing results had outrun that of interpreting them. But at last came the complete explanation of the impossible quantity [ALGEBRA], showing that all the difficulty had arisen from too great limitation of definitions; and almost about the same time arose that disposition among the continental writers, of which we have spoken above, namely, to wait no longer for the explanation of the true meaning of a divergent series, but to abandon it altogether. But why should the divergent series, of all the results of algebra which demand interpretation, be the only one to be thrown away without further inquiry, when in every other case patience and research have brought light out of darkness.

So far as the matter has yet gone, very little has been done towards the interpretation of a divergent series independently of its involopment, or function from which it is developed. When this involopment is known, and the series deduced from it, there are means of stopping the divergency, by arresting the development at any given point, and turning the remainder, not into a further development, but into a finite form. Thus if ϕx, a given function of x, should give a divergent series $\mathrm{A}_0+\mathrm{A}_1x+\ldots\ldots$, all that part of the development which follows $\mathrm{A}_n x^n$ may be included in

$$\int_0^x \phi^{(n+1)}(x-v)\,v^n dv\ :\ 1.2.3\ldots\ldots n.$$

This will be proved in TAYLOR'S THEOREM, and it is a result of great importance, because it gives the means of removing all the doubtful points of divergent series from the ordinary branches of mathematics.

Next to the question of convergency or divergency, comes that of continuity or discontinuity. We are not here speaking of continuity of value, but of form. A series is continuous when for all values of x it represents the same function of x. Thus $\mathrm{s}_0 x^n$ or $x^0+x^1+x^2+\ldots$, is in all cases the development of $(1-x)^{-1}$, whether it be convergent or divergent. Even those who reject divergent series altogether, though they would call this series, when $x>1$, a false or inadmissible development of $(1-x)^{-1}$, would not, though they reject it, look upon it as possible to arise from any other function. But the series

$$\mathrm{s}_1(-1)^{n+1}\frac{\sin n\theta}{n}\ \text{or}\ \sin\theta-\frac{\sin 2\theta}{2}+\frac{\sin 3\theta}{3}-\ldots$$

is discontinuous; for certain values of θ it represents one function, and for other values another. When θ is any multiple of π [ANGLE] it is $=0$; when θ falls between $-\pi$ and $+\pi$, it is $\frac{1}{2}\theta$; when θ falls between π and 3π, it is $\frac{1}{2}\theta-\pi$, &c.; in fact, it stands for $\frac{1}{2}\theta-m\pi$, where m is to be so taken that $\frac{1}{2}\theta-m\pi$ shall fall between $-\frac{1}{2}\pi$ and $+\frac{1}{2}\pi$. Again, the series

$$\mathrm{s}_0\frac{a^n x}{(1+a^n x)(1+a^{n+1}x)}=\frac{1}{(a-1)(x+1)}\ \text{or}\ \frac{x}{(1-a)(x+1)}$$

according as $a>1$ or <1: and when $a=1$, it is infinite. Remember that by calling a series infinite we do not merely mean that it is divergent, for a divergent series may be the development of a finite quantity; thus $1+2+4+\ldots\ldots$ is a development of -1 from the form $(1-2)^{-1}$. But we mean that the *arithmetical value* of the function developed is infinite when we say that the series is infinite.

Discontinuity of form may be in many cases avoided by an extension of the modes of algebraical expression. Thus if we write down the expression

$$\frac{1}{a-1}\left\{\frac{1}{x+1}-\frac{1}{a^k x+1}\right\}$$

and consider k as having a very great value, the second term will be very small or very near to unity, according as a is >1 or <1. If we introduce the symbol a^∞ as representing ∞ when $a>1$, and 0 when $a<1$, we have, on putting ∞ for k, the representation of both forms of the preceding series in one. We shall now proceed to point out some of the principal modes of transforming series into others, or deducing others from them, so far as this is done without interfering with the developments in TAYLOR'S THEOREM.

1. If ϕx can be developed into $a+a_1x+a_2x^2+\ldots$, then $ab+a_1b_1x+a_2b_2x^2+\ldots$ can be developed as follows (D. C., p. 239). Let the last be ψx, and from b, b_1, b_2, &c. [DIFFERENCE] form Δb, $\Delta^2 b$, &c.: then

$$\psi x=b\phi x+\Delta b\,.\,x\phi' x+\frac{\Delta^2 b}{2}x^2\phi'' x+\frac{\Delta^3 b}{2\,.\,3}x^3\phi''' x+\ldots$$

where $\phi' x$, $\phi'' x$, &c., are the successive differential coefficients of ϕx. If b, b_1, &c. be values of a rational and integral function of n, denoted by b_n, the preceding is not an infinite series, but a finite expression. We have not room for examples, and it is to be remembered that this is an article of reference. Particular classes of instances are

$$b+b_1x+\ldots=\frac{b}{(1-x)}+\frac{\Delta b\,.\,x}{(1-x)^2}+\frac{\Delta^2 b\,.\,x^2}{(1-x)^3}+\ldots$$

$$b+nb_1x+n\frac{n-1}{2}b_2x^2+n\frac{n-1}{2}\frac{n-2}{3}b_3x^3+\ldots=$$

$$(1+x)^n\left\{b+n\Delta b\frac{x}{1+x}+n\frac{n-1}{2}\Delta^2 b\left(\frac{x}{1+x}\right)^2+\ldots\right\}$$

$$b+b_1x+b_2\frac{x^2}{2}+b_3\frac{x^3}{2\,.\,3}+\ldots=\varepsilon^x\left(b+\Delta bx+\Delta^2 b\frac{x^2}{2}+\ldots\right)$$

the preceding is a case of more general theorem (D. C., p. 565) from which the following may also be deduced:—

$$b+b_1x+\ldots=\frac{b}{1+mx}+\frac{\nabla b\,.\,x}{(1+mx)^2}+\frac{\nabla^2 b\,.\,x^2}{(1+mx)^3}+\ldots$$

$\nabla b=b_1+mb$, $\nabla^2 b=b_2+2mb_1+m^2b$, &c. By this theorem many divergent series may be converted into convergent ones, or the convergency of convergent series may be increased.

2. Let $r=\sqrt{(1-2\cos\theta\,.\,x+x^2)}$, $\tan\phi=\dfrac{x\sin\theta}{1-x\cos\theta}$.

Then $b+b_1\cos\theta\,.\,x+b_2\cos 2\theta\,.\,x^2+b_3\cos 3\theta\,.\,x^3+\ldots=$

$$\cos\phi\frac{b}{r}+\cos(\theta+2\phi)\frac{\Delta bx}{r^2}+\cos(2\theta+3\phi)\frac{\Delta^2 b\,.\,x^2}{r^3}+\ldots$$

and $b_1\sin\theta\ x+b_2\sin 2\theta\,.\,x^2+b_3\sin 3\theta\,.\,x^3+\ldots=$

$$\sin\phi\frac{b}{r}+\sin(\theta+2\phi)\frac{\Delta b\,.\,x}{r^2}+\sin(2\theta+3\phi)\frac{\Delta^2 b\,.\,x^2}{r^3}+\ldots$$

3. Let ϕx be a rational and integral function of x; then

$$\phi x+\phi(x+1)\,.\,a+\phi(x+2)\,.\,a^2+\ldots=\frac{1}{1-a}\phi x+$$

$$\frac{a}{(1-a)^2}\phi' x+\frac{a+a^2}{(1-a)^3}\frac{\phi'' x}{2}+\frac{\mathrm{A}_3}{(1-a)^4}\frac{\phi''' x}{2\,.\,3}+\ldots.$$

$$\mathrm{A}_3=a+4a^2+a^3,\ \mathrm{A}_4=a+11a^2+11a^3+a^4$$

$$\mathrm{A}_5=a+26a^2+66a^3+26a^4+a^5,\ \text{\&c.}$$

$$\mathrm{A}_6=a+57a^2+302(a^3+a^4)+57a^5+a^6.$$

This must lead to a finite expression for the series, and is frequently the shortest way of obtaining it.

4. Let $z = \epsilon^{\theta\sqrt{-1}} = \cos\theta + \sqrt{-1}\,.\,\sin\theta$ and $\phi x = a + a_1 x + a_2 x^2 + \dots.$

$$\frac{1}{2}\left\{\phi(zx) + \phi\left(\frac{x}{z}\right)\right\} = a_0 + a_1 \cos\theta\,.\,x + \dots.$$

$$\frac{1}{2\sqrt{-1}}\left\{\phi(zx) - \phi\left(\frac{x}{z}\right)\right\} = a_1 \sin\theta\,.\,x + \dots.$$

the series resembling those in (2). Further varieties will appear in TAYLOR'S THEOREM.

5. If $\phi(0) + \phi(1)\,.\,x + \phi(2)\,.\,x^2 + \dots.$ be the development of a perfectly continuous function of x, and if ϕn be a function which never becomes infinite for any real value of n, positive or negative; then the same function may be also developed into $-\phi(-1)\,.\,x^{-1} - \phi(-2)\,.\,x^{-2} - \phi(-3)\,.\,x^{-3} - \dots.$ (D. C., p. 560).

6. If $\phi x = a_0 + a_1 x + a_2 x^2 + \dots.$ and if $\rho_1, \rho_2, \dots \rho_n$ be the n nth ROOTS of unity, then (D. C., p. 319)

$$a_0 + a_n x^n + a_{2n} x^{2n} + \dots = \frac{\phi(\rho_1 x) + \dots + \phi(\rho_n x)}{n}$$

$$a_1 x + a_{n+1} x^{n+1} + \dots = \frac{\rho_1^{\,n-1}\phi(\rho_1 x) + \dots + \rho_n^{\,n-1}\phi(\rho_n x)}{n}$$

$$a_2 x^2 + a_{n+2} x^{n+2} + \dots = \frac{\rho_1^{\,n-2}\phi(\rho_1 x) + \dots + \rho_n^{\,n-2}\phi(\rho_n x)}{n}$$

and so on. Also if we make ρ_1, ρ_2, &c., the nth roots of -1, and use the same results, only altering the multipliers into $\rho_1^{\,2n-1}$, &c., $\rho_1^{\,2n-2}$, &c., we have the sums of the same series with the terms alternately positive and negative.

7. One of the simplest modes of actually finding a finite expression for a series, finite or infinite, the coefficients of which are values of a rational and integral function, is the continual multiplication by $1-x$, which must at last produce a finite expression. It must be remembered that multiplication by $1-x$ may be performed by letting the first coefficient remain, and diminishing every other coefficient by its predecessor. Thus $a + bx + cx^2 + ex^3 + \dots.$ multiplied by $1-x$ gives $a + (b-a)x + (c-b)x^2 + (e-c)x^3 +$. And a finite series must be supposed to be continued *ad infinitum* with vanishing coefficients. For example, it is required to find a finite expression for $1^3 + 2^3x + 3^3x^2 + \dots$; write this as in the first line, and make successive multiplications by $1-x$, as in the following lines:—

$$\begin{array}{l} 1 + 8x + 27x^2 + 64x^3 + 126x^4 + \dots \\ 1 + 7x + 19x^2 + 37x^3 + \;\; 61x^4 + \dots \\ 1 + 6x + 12x^2 + 18x^3 + \;\; 24x^4 + \dots. \\ 1 + 5x + \;\; 6x^2 + \;\; 6x^3 + \;\;\; 6x^4 + \dots. \\ 1 + 4x + \;\;\; x^2 + \;\; 0x^3 + \;\;\; 0x^4 + \dots. \end{array}$$

After four multiplications, then, by $1-x$, the series becomes $1 + 4x + x^2$; whence its value is—

$$\frac{1 + 4x + x^2}{(1-x)^4}$$

Independently of the modes of deriving series obtained from Taylor's Theorem, and of which we are to speak elsewhere, there are two modes of forming them which deserve attention. The first depends upon the numbers called the differences of nothing [NOTHING, DIFFERENCES OF]; the second on those called NUMBERS OF BERNOULLI.

By the first of these any function of ϵ^x can be expanded in powers of x.

$$f\epsilon^x = f1 + f(1+\Delta)\,0\,.\,x + f(1+\Delta)\,0^2\,.\,\frac{x^2}{2} + \dots$$

Here $f(1+\Delta)\,0^n$ is a symbol of the calculus of operations [OPERATION], which expanded is—

$$f1\,.\,0^n + f'1\,.\,\Delta 0^n + \dots. + f^{(n)}1\,\frac{\Delta^n 0^n}{2\,.\,3\dots n}$$

it being unnecessary to go further, because $\Delta^m 0^n = 0$ whenever m is greater than n. (D. C., 307.)

The numbers of Bernoulli occur first in the development of $(\epsilon^x - 1)^{-1}$, a series the importance of which can only be estimated by its use in SUMMATION. Taking the numbers from the article cited above, or making

$$B_1 = \frac{1}{6}\;,\;\; B_3 = \frac{1}{30}\;,\;\; B_5 = \frac{1}{42}\;,\;\; B_7 = \frac{1}{30},\ \&c.$$

$$\frac{1}{\epsilon^x - 1} = \frac{1}{x} - \frac{1}{2} + \frac{B_1 x}{2} - \frac{B_3 x^3}{[4]} + \frac{B_5 x^5}{[6]} - \dots.$$

$$\frac{1}{\epsilon^x + 1} = \frac{1}{2} - \frac{3B_1 x}{2} + \frac{15B_3 x^3}{[4]} - \frac{63B_5 x^5}{[6]} + \dots.$$

where $[n]$ means $1\,.\,2\,.\,3\,\dots.\,n-1\,.\,n$.

We shall now give a number of series which are not of very frequent use, but which may sometimes be sought in a work of reference. Under the last predicament we can never suppose that any of the following developments would come: $(1+x)^n$, ϵ^x, a^x, $\log(1+x)$, $\log\frac{1+x}{1-x}$, $\sin x$, or $\cos x$. Some terms are given, and $\pm\dots.$ is omitted to save room.

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \frac{62x^9}{2835} + \frac{1382x^{11}}{155925}$$

$$\cot x = \frac{1}{x} - \frac{x}{3} - \frac{x^3}{45} - \frac{2x^5}{945} - \frac{x^7}{4725} - \frac{2x^9}{93555}$$

$$\sec x = 1 + \frac{x^2}{2} + \frac{5x^4}{24} + \frac{61x^6}{720} + \frac{277x^8}{8064}$$

$$\operatorname{cosec} x = \frac{1}{x} + \frac{x}{6} + \frac{7x^3}{360} + \frac{31x^5}{15120} + \frac{127x^7}{604800}$$

$$\sin^{-1} x^{*} = x + \frac{1}{2}\frac{x^3}{3} + \frac{1\,.\,3}{2\,.\,4}\frac{x^5}{5} + \frac{1\,.\,3\,.\,5}{2\,.\,4\,.\,6}\frac{x^7}{7}$$

$$\tan^{-1} x^{*} = x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7}$$

$$\log\frac{x}{\sin x} = \frac{x^2}{6} + \frac{x^4}{180} + \frac{x^6}{2835} + \frac{x^8}{37800} + \frac{x^{10}}{467775}$$

$$\log\frac{1}{\cos x} = \frac{x^2}{2} + \frac{x^4}{12} + \frac{x^6}{45} + \frac{17x^8}{2520} + \frac{31x^{10}}{14175}$$

$$\log\frac{\tan x}{x} = \frac{x^2}{3} + \frac{7x^4}{90} + \frac{62x^6}{2835} + \frac{x^8}{2700} + \frac{32x^{10}}{467775}$$

These logarithms are the Naperian logarithms, as is always the case in analysis, unless the contrary be expressed (as it is usual to say, but it really never happens):

$$\frac{1}{\log(1+x)} = \frac{1}{x} + \frac{1}{2} - \frac{x}{12} + \frac{x^2}{24} - \frac{19x^3}{720} + \frac{3x^4}{160} - \frac{863x^5}{60480}.$$

We must again remind the reader that the symbol $+$, &c., or $-$, &c., is throughout omitted to save room.

There is one property of series which deserves particular notice (D. C., pp. 226 and 649) as creating a most remarkable distinction between those which have all their terms positive, and those which have them alternately positive and negative. The former, even if the terms diminish without limit, are not necessarily convergent; thus $1 + 2^{-1} + 3^{-1} + \dots.$ is divergent. But if the terms be alternately positive and negative, and diminishing without limit, the series is always convergent, and the error made by stopping at any term is less than the first of the terms thrown away. And the most remarkable part of the property is that this last is true, even if the series become divergent, by having its terms increasing without limit, instead of diminishing; so that if the terms diminish for a time, and then begin to increase, the portion of the series during which the diminution takes place may be made use of in approximating to its arithmetical value. That is, if A_1, A_2, be all positive quantities, and if the infinite series $A_1 - A_2 + A_3 - \dots.$ be carried as far as A_n, the error is less than A_{n+1}, whatever the law of the terms may be, or however rapidly they may afterwards increase. Let us take, for instance,—

$$1 - \frac{2}{x} + \frac{2\,.\,3}{x^2} - \frac{2\,.\,3\,.\,4}{x^3} + \frac{2\,.\,3\,.\,4\,.\,5}{x^4} - \dots.$$

Let x be ever so great, the rapid increase of the numerators must still make this series ultimately divergent. Nevertheless, if x be considerable, the first terms diminish so rapidly that, with the aid of the above theorem, a good approximation may be made to the arithmetical value of the function from which the series was derived. Let $x = 100$, whence the series becomes—

$$1 - \cdot02 + \cdot0006 - \cdot000024 + \cdot00000120 - \dots.$$

After the hundredth term the terms will begin to increase, and more and more rapidly; but the theorem enables us, when $x = 100$, to make the following assertions; first, 1 is too great, but not by so much as ·02; 1 − ·02, or ·98, is too small, but not by so much as ·0006; ·98 + ·0006, or ·9806, is too great, but not by so much as ·000024; ·9806 − ·000024, or ·980576, is too small, but not by so much as ·00000120; ·980576 + ·00000120, or ·9805772, is too great, but not by so much as the next term; and so on.

SERJEANT, or SERGEANT (*Serviens*). This term, in its original signification, has long become obsolete. It would however be difficult to trace the connection between the different officers to whom the term is now applied without going back to their common type.

The term serviens and servicium appear to have been applied at first to all servants of the public, or of the crown, as the head of the state, and to the service rendered by them as an acknowledgment or render for the lands held by such service. Rent paid by a tenant to his landlord is still distinguished by the name of rent-service [RENT] from other annual payments charged upon land, &c. The word "serjeant" comes to us from "sergent," into which the French had modified the Latin "serviens." The word serjeanty, in French "sergenterie," was

---

[*] In these series the angle is less than a right angle, positive or negative.

formed from "sergent," but was always used with reference to a particular species of service.

The complete development of the feudal system which followed the Norman conquest, was greatly facilitated by those political struggles which terminated in placing large portions of the lands of the kingdom in succession at the disposition of the crown. The forfeited lands of the revolted English were granted by the Conqueror to his followers with few exceptions, subject to the performance of personal services regulated by the quantity of the land granted and the rank and qualification of the grantee. The services ordinarily reserved upon grants by the crown, and upon those made by inferior grantors to their military followers, were of a military character. Where the grant was to hold by the service of a knight's fee, or of two, or half a knight's fee, &c., without expressing the nature of the service to be performed, the party was said to hold by knight's service, *per servicium militare* [KNIGHT'S SERVICE]; but where some *particular* service was to be performed by the tenant, or by some duly qualified person provided by him,—as, to be an earl or baron of the realm, to lead the king's host, to assist in the defence of a certain castle, to wind a horn upon an invasion, &c.—the tenure was called tenure by serjeanty (*per serjeantiam*), and the grantee became a tenant by serjeanty, and would be a serjeant (*serviens*). Whilst the two tenures were always distinguished by the two appellations of "serjeantia" and "servicium militare," the term "serviens" or "serjeant" was applicable to a tenant belonging to either class who had not taken upon himself the order of knighthood.

As the tenant by serjeanty was commonly distinguished by some title derived from the nature of his service—as earl, baron, constable, marshal, treasurer, &c.—the name "serjeant" was usually applied, not to those who held in serjeanty, but to those who held *per servicium militare* generally, and had not been knighted. Thus in 1348 the four knights impanneled on a grand assize were told by the judge that they should elect no serjeants whilst they could find suitable knights (M. 22 Edw. III., fo. 18); and in 1352 the four knights, not being able to elect twelve other knights, were allowed, by the assent of parties, to elect of the most wealthy serjeants (H. 26 Edw. III., fo. 57, pl. 12). (These two cases have been strangely misunderstood by Dugdale and others, as if they related to an exemption of serjeants-at-law from the burthen of serving upon a grand assize.) So an ordinance was made in parliament in the reign of Edward III. (1362), by which the return of lawyers to parliament, as knights for counties, was prohibited, on the ground that they acted with a view rather to the benefit of their clients than to that of the public, and the elections were directed to be made of knights and of serjeants of the most value. The term serjeant is also applied to those inferior military tenants, in the grant of a subsidy in 1379, in which serjeants and franklins of the county are assessed at 6*s.* 8*d.*, or 3*s.* 4*d.*, according to their estate, whilst serjeants at law are assessed at a fixed sum of 40*s.*, being twice the amount of the assessment of barons of the realm. (3 'Rot. Parl.,' 58.)

The serjeant holding *per servicium militare*, if possessed of sufficient land, was however bound, when called upon, to take upon himself the obligations attendant upon the order of knighthood. The tenant, or expectant tenant of such an estate, who wished to qualify himself for the creditable discharge of knightly duties, usually entered upon a course of training in the capacity of esquire to some knight, into whose service he was induced to enter by considerations arising from family connection, tenure, or friendship, or from the opinion entertained of his military fame. Although from the time of the Conquest down to the latter end of the reign of Edward III. all military tenants who had not been knighted are designated "serjeants," we find that after the first years of the reign of Richard II. the term serjeant, as applied to the unknighted tenant by knight's service, disappears, and is succeeded by the "esquire," a term previously used not to designate a class of persons occupying a certain rank, but an office actually performed. ('Abb. Rot. Origin.,' 209, b.) The services of the serjeant of the 14th century, and those of his successor, the esquire of the 15th, were alike estimated as equal to one-half of the service of a knight-bachelor, or one-fourth of the service of a knight-banneret.

A special service of a military character, to be performed by the tenant or his sufficient deputy, was not less noble than the ordinary knight's service, and was sometimes called chivalerian serjeanty, but more commonly grand serjeanty. It is said, indeed, by Littleton (s. 153) to be a greater and more worthy service than the other. But any service, military or civil, which was to be performed by the tenant or his deputy to the king himself, was, on account of the dignity of the king's person, accounted a grand or chivalerian serjeanty. Thus, in the Germanic body, the offices of arch-chancellor, arch-treasurer, arch-butler, &c., of the empire, attached to particular electorates, were of equal dignity with that of arch-marshal of the empire held by another elector; and in England, the civil office of lord high treasurer, &c., the military office of lord high constable, &c., and the mixed office of lord high steward, &c., and that of earl or baron by tenure, are, or were, all equally held by grand serjeanty.

Lands held by serjeanty, on account of the entire nature of the service, could not lawfully be aliened or divided. This, however, was by a species of connivance frequently done in fact. The course was for the crown to issue a commission to fix a rent upon the alienated serjeanty, or the divided portions. By this process, tenancies in serjeanty gradually became nearly extinct before the abolition of military tenures. Sometimes, upon the escheat or forfeiture of a serjeanty, the lands were granted by the crown, to hold by knight's service, whereby the special service of the serjeanty was lost.

Where the services reserved upon the tenure bore some relation to war, but were required neither to be executed personally by the tenant or his deputy, nor to be performed to the person of the king, as the payment of rent in spurs, arrows, &c., the tenant was said to hold by *petit* or *petty* serjeanty, which was a socage tenure, having the same non-military incidents as a tenure upon which an annual rent in money, corn, &c., was reserved, though considered to be of a somewhat more dignified character.

The tenant in serjeanty was bound either to perform the special service himself, or to provide a person competent to discharge it. Sometimes, the land having descended to or been acquired by a citizen or a burgess, the service was considered of too great dignity to be performed by the tenant upon whom the duty of the serjeanty had thus devolved, in which case he was required to appoint a competent substitute. It happened more frequently, however, that the service to be performed was below the serjeant's rank, in which case it was permitted and expected that the service should be performed by deputy. This became so much a matter of course, that we find lands held in serjeanty commonly described as held by the service of procuring (per servicium inveniendi) persons to do the duty. This frequently happened with regard to the inferior offices relating to the administration of the law, as in the ordinary case of a tenure by the service of finding bailiffs itinerant. With respect to this particular appointment and some few others, the name itself was transferred from the appointer to the appointee, and the designation of serjeant was given to the person by whom the service of the serjeanty was actually performed. Hence our serjeants-at-mace, and other similar officers in Normandy and in England. In like manner, the sheriff being the ballivus of the county,—that is, the person into whose custody or bailiwick the county is *bailed* or delivered,—the inferior officers whom he employs have acquired the name of bailiffs. However humble the nature of the service may have been, the tenant was bound to perform it in person, in case no substitute could be obtained.

Among the civil services the performance of which was provided for by the creation of serjeanties, one of the most important was the administration of justice. Both in Normandy and in England numerous grants of lands were made, to which grants the obligation to discharge certain judicial or ministerial duties was annexed in lieu of the ordinary knight's service. In both countries it would appear that all counties, as well as the more important cities and boroughs, were placed under an officer of the crown who held lands by the tenure of administering justice in criminal matters. This local judge was in England called the king's serjeant (serviens regis), or the serjeant of the county, city, or borough; sometimes (stat. Westm. I., c. 30) serjeant in fee; sometimes capitalis serviens of the county ('Rot. Parl.,' 236) or of the hundred ('Testa de Nevil,' 409 d).

Lands held by this tenure are commonly described in ancient records as lands held per serjeantiam tenendi (sometimes custodiendi) placita coronæ. It appears from Bracton, fol. 157, that this officer (the king's serjeant) had a concurrent jurisdiction with the sheriff, and that their records were equally incapable of being controverted. These serjeants had officers under them, who, taking the denomination of serjeant from the hereditary officer whose authority was in part delegated to them, were in counties known by the name of serjeants of the sword, sergens de l'espee, servientes ad spatam, and in cities and boroughs by the name of serjeants-at-mace, servientes ad clavam. In the course of time, as charters were obtained, the citizens and burgesses acquired the right of choosing their own magistrates; and the king's officer, the serjeant, was superseded by the municipal officers, the mayor and aldermen. It is said that Norwich had no magistrate, except the king's serjeant, until the 17th year of King Stephen. (Stow, 214; Spelman, 'Gloss.') It sometimes happened that, after the incorporation of the city or town, the serjeant continued to be the judicial officer *de facto*, sitting as assessor to the municipal magistrates. This was the case at Oxford. ('Harleian MSS.,' 298, fol. 56.) In London the office appears to have been retained, but a charter of 12 Edw. II. gave to the citizens the privilege of electing their *common serjeant*.

In counties, the king's serjeant, as a judicial officer, may be traced to a much later period; and although the office is now become obsolete, and its principal functions have for centuries devolved upon the justices of the peace, proclamation is still made upon the execution of every commission of jail delivery, inviting all persons to inform this officer of any treason, felonies, or misdemeanors committed by the prisoner at the bar.

Where the criminal jurisdiction of a particular district was annexed to a grant of land to a subject, the jurisdiction, though imposed as a condition and a burden, was called a franchise [FRANCHISE], inasmuch as it excluded the ordinary power of the officers of the crown. The grantee was said to hold in frank serjeanty, en franche sergenterie; and in respect of the lands attached to the office, this serjeanty was in Normandy sometimes called une sergenterie glèbée. For the actual administration of justice, the tenant usually delegated his judicial authority as serjeant to an officer of his own, who was therefore called *his* serjeant, or the serjeant of the district (Mad. 'Exch.,' 103; 'Testa de Nevil,' 389), or serjeant of the peace for the district. (Cowell, 'Interpr.') Hence, the steward of a private leet, or of a manor to which a leet is attached, to whom the lord always delegates his judicial power, is sometimes designated as serviens sive senescallus. (4 Co., 'Rep.,' 21.) Latterly, indeed, it has been considered that a tenure by serjeanty could only be created by, and held under, the crown. (Co. Litt., 108 a.) This was not the case, however, in the time of Henry III., as appears by Bracton (35 b.).

The tenure, by which lands were held by a "serjeant of the county," or "serjeant in fee," was a serjeanty belonging to that class which was called grand serjeanty, as being connected with the administration of justice. Edmund, earl of Lancaster, brother of Edward I., died seised "de magna sergeantia totius comitatus de Derby." ('Calend. Inquis. post. mortem,' 136, b.)

But the serjeants of counties were neither the only nor the most numerous class of serjeants-at-law. The main branch of that body remained in attendance upon the king. Their duty was to assist in the proceedings of the Aula Regia, the great court of justice of the realm, as assessors to the chief justiciar, and as advocates for the suitors, who being generally unacquainted with the language in which the proceedings of the court were carried on, were seldom able, and were never permitted, to plead their own causes. (1 'Rot. Parl.,' 4 a; 2 'Rot. Parl.,' 140.) Upon the breaking-up of the Aula Regia into the several courts which now occupy Westminster Hall, the serjeants-at-law became the justices of the courts of King's Bench and Common Pleas, and acted as advocates for the suitors, when not appointed to those offices, and when removed from them. While not employed in judicial stations, they were called serjeant-countors, servientes-narratores, and banci narratores, countor (narrator) being a term derived from the Norman "conteurs," persons whose office it was to conduct the causes of litigants in court, the verb "conter" being applied indifferently to the pleadings on the part of the plaintiff and those on the part of the defendant.

It does not distinctly appear whether any grants of land were annexed to the office of serjeant-countor; if not, it is probable that the Conqueror, or some of his early successors, considered the fees receivable by the serjeant-justices and the serjeant-countors as equivalent to a grant of lands, and as constituting a serjeanty not attached to a tenure of land, or a serjeanty in gross. However this may be, the kings exercised the right of creating both serjeant-justices and serjeant-countors. The appointment of serjeant-countor has, from the earliest period, been effected by the royal mandate under the great seal; by writ, where the party to whom it was addressed was required to serve the king and his people in the Aula Regis, and afterwards in the courts of Westminster Hall; by letters-patent, with respect to serjeants in Ireland. Under this appointment, the serjeants were the sole public pleaders. They were the only persons in the state entrusted with the exercise of the ordinary judicial functions, and even now no person can be appointed a justice of the Queen's Bench or Common Pleas, who is not of the degree of the coif, that expression being derived from the peculiar species of cap which was, and still is, the distinguishing dress of serjeants-at-law. The barons of the Exchequer who were formerly merely officers of revenue, are not required to be taken from amongst the serjeants; but unless they were of the degree of the coif, they were not qualified to act as justices of assize. Although the serjeants on the circuit, and the queen's counsel, and occasionally other barristers, are included in the commissions of oyer and terminer, and jail delivery, and assist in the trying of prisoners when the judges are pressed for time, or if it is thought desirable to relieve the county from the expense arising from the detention of prosecutors and witnesses, the name of no person who is not a serjeant or queen's counsel, or possesses a patent of precedence, can be inserted in the commission of assize. Formerly no one but a serjeant was so qualified. (13 Edw. I. st. i., c 30; 13 & 14 Vict. c. 25.)

Much obscurity however still hangs over the origin of the connection between the terms serjeant and countor. It has been suggested that upon the introduction of the Norman conteurs in England, they were formed into a lay brotherhood, somewhat analogous in form to the religious communities by which they were surrounded; that the members of this brotherhood were admitted by royal authority, and employed in different capacities as judges and advocates about the Aula Regia; and that they probably derived their adjunct title of servientes from the nature of their employment, and from the circumstance of their appointment being conferred by the crown, and of its being considered that the services which they rendered were of equal dignity and importance with services reserved upon those tenures by grand serjeanty to which administration of justice was attached, and the tenants of which were in strict propriety denominated serjeants.

Upon the calling of every parliament, the judges and serjeants are summoned by writ to give their attendance. Their principal duty appears to have been to assist the lords in the trials of petitions. ('Rot. Parl.' *passim.*) The writ of summons issues to the judges, not as judges, but as serjeants; and if a baron of the Exchequer be not a serjeant, as was formerly often, and still may be, the case, he is not summoned. No serjeants have been required to attend of late years, except judges and queen's serjeants, but formerly other serjeants were also summoned.

Whilst the Aula Regis constituted one court, a second class of advocates was little needed; and upon that court being afterwards divided into different sections or branches, no inconvenience appears to have been felt, as all the different sections of the court equally followed the person of the king. But when, in the reign of Edward I., the regulation for holding common pleas, that is, all *civil* actions, in some certain place to be appointed by the crown, was put in force, parties who had business in the court of King's Bench, the jurisdiction of which, except occasionally as a court of appeal, was then almost confined to criminal matters, or in the court of Exchequer, the jurisdiction of which related to matters of revenue, or in the court of Chancery, were put to inconvenience for want of advocates, as often as the king, whose progresses these courts still followed, happened to be distant from the place (usually Westminster Hall, and seldom elsewhere, after the reign of Edward III.) at which the court of Common Pleas sat. To remedy this inconvenience, and at the same time to relieve parties from the burdensome duty of appearing in person in the court of Common Pleas, an ordinance was made in Parliament, in 1292, by Edward I., by which the king directed the selection of a number (fixed provisionally at 140) from the higher class of legal students to act both as attorneys in the stationary court of Common Pleas, and as advocates in the comparatively few cases which then required their assistance in the ambulatory courts of the King's Bench, Chancery, and Exchequer. No distinction is made in the ordinance between attorneys and apprentices, and the 140 appear to have acted indiscriminately (2 'Rot. Parl.', 96) as attorneys and as advocates, as their services happened to be required. Complaints were however still made in Parliament (1364-5) of the prejudice arising to parties implicated in proceedings in the two latter courts, from being unable to procure the assistance of serjeants; and it was prayed, though unsuccessfully, that on this ground these courts might also be made stationary.

A petition of the Commons in 1343, that parties to suits in the Marshalsea might be allowed to plead their own causes in that court, in order that they might not be delayed for want of serjeants, had met with a more favourable reception, and the permission was granted by an act of parliament (2 'Rot. Parl.,' 140), which act was not in print till the parliament rolls were published at the commencement of the present century. It was a punishable contempt of the court for a person to interfere as advocate without possessing a legal title to the office. ('Abb. Placit. in Dom. Cap. Westm.,' 137.)

It is stated in the article Barrister, that serjeants and apprentices at law were supposed by Dugdale to be the same persons. Dugdale relies upon the circumstance that in the second year of Henry VI. an apprentice was heard in the court of Common Pleas, where serjeants alone practised. But Dugdale was mistaken in supposing that the apprentice acted as an advocate in that court; for upon reference to the 'Year-Book' (M. 2 H. 6, fol. 5, pl. 3), it will be seen that this apprentice was merely sent by the Exchequer into the Common Pleas to ask the opinion of the judges and serjeants in the latter court upon a point of law then depending in the Exchequer; upon which the judges of the Common Pleas consulted the serjeants, and the point was debated by judges and serjeants indiscriminately. The apprentice took no part in the discussion, but carried back the result to the Exchequer, upon which that court acted. It has also been supposed that Plowden and Carrel, who are spoken of as apprentices in 4 Eliz., (1562), were at that time serjeants. With respect to the former, the mistake arose from the circumstance that a writ issued to Plowden and eleven others, in October, 1558, calling upon them to be made serjeants in Easter following. Mary dying in November, 1558, the writs abated. In 1559 fresh writs were issued by Elizabeth to seven of the eleven, but the names of Plowden and four others, as may be seen in Dugdale, were omitted. Plowden therefore remained an apprentice as before, and he is properly so designated in 4 Eliz. (1562). With respect to Carrel also, we have no distinct proof that he ever took the degree of serjeant, though it seems not improbable that he was often commanded so to do. John Carrel received a writ requiring him to take the degree of a serjeant in 1540, and again in 1552 and 1554. In what manner he was excused on these occasions, and whether he paid more attention to Mary's commands than he had done to those of her father and brother, or whether indeed the Carrel apprentice in 1562 was the same person with John Carrel, the serjeant thrice elect, does not appear.

The ordinance of Edward I. authorised only students who had reached the rank of "apprentices at law" to practise as advocates in those courts in which the assistance of serjeants could not constantly be obtained; but as the practice of these courts increased, it was found necessary, in the reign of Elizabeth, to allow persons of less standing than apprentices to act both as advocates and as attorneys.

Students who, though not yet apprentices at law, had been admitted to argue fictitious cases at the mootings in their respective inns of court, were allowed to practise as advocates in the ambulatory courts of common law and equity. Advocates of this third class were called utter-barristers, because in arguing their moot cases by way of preparation for real forensic debates they were placed at the outer or uttermost end of the form on which they sat, and which was called the "barr." (Stow; Waterhous; Dugdale; Herbert, 'Antiq. Inns of Court,' 176.) The junior students, who sat in silence on the inside, were called inner-barristers. But the latter term has long been abandoned, and is sunk in the more general designation of student; in consequence of which the term utter-barrister has also given place to that of barrister, and the student who is admitted to that degree is said to be "called to the bar." This call however consists merely in the presiding bencher's saying, "I publish you a barrister of this Society."

The mere students, formerly called inner-barristers, confine themselves to study, or, when they consider themselves qualified, practise as conveyancers, special pleaders, or equity draftsmen, in which capacity they are recognised by the legislature, being required to take out annual certificates from the stamp-office. For nearly the last forty years students practising as certificated special pleaders have been allowed to practise as advocates before judges sitting in their private chambers at Serjeants' Inn, for the summary despatch of matters of pleading and practice, &c.

Shortly after the permission given to barristers to practice as advocates, we lose sight of the order of apprentices. Though usual, it was never perhaps absolutely necessary that a student should become an apprentice in order to qualify him for being called to the degree of the coif; and when it ceased to be required as a title to practise as an advocate, there was no longer any motive for taking the degree of an apprentice.

The result of these inquiries seems to be, that from the Conquest to the 20 Edw. I. (1292), serjeant-countors were the only advocates; that from 1292 to the latter end of the 16th century, apprentices were allowed to practise in certain courts; that towards the close of the 16th century, the apprentices were supplanted by a more numerous class of junior students called utter-barristers and afterwards barristers; and that from the middle of the 18th century, mere students were at any time after their admission, and immediately upon their admission, allowed to practise as certificated conveyancers or certificated special pleaders; and that such special pleaders have latterly been allowed to practise as advocates before judges when administering justice in their private chambers; which latter practice may be thus explained:—The business to be disposed of by the courts at Westminster having far outgrown the machinery provided for its despatch, many acts of parliament have directed that certain judicial acts shall be done by the court "or any judge thereof." The consequence of these provisions, and of a practice existing before, of referring minor questions and cases of a pressing nature to be disposed of by a single judge, has been that a most important part of the judicial business of the country, instead of being discussed as formerly in open court before a full bench, and with the assistance or in the presence of an intelligent bar, is commonly disposed of by a single judge in a private room, without any assistance except that which he can derive from the attorney's clerks on each side who attend the summons. It not unfrequently happens that a most abstruse point of special pleading, involving the fate, and sometimes the real merits of the cause, and which in the reign of Edward VI. would have been argued by learned serjeants and *sad* apprentices at the bar, and afterwards debated publicly on the bench, is disposed of in five minutes, and without appeal, at chambers by a judge who has never practised this branch of the law, and who would when at the bar have shrunk from the responsibility of expressing an opinion on the most ordinary question connected with the science of special pleading. It was therefore quite natural that judges should be glad to avail themselves at chambers of the assistance of special pleaders; and in order to prevent the abuse of the indiscriminate invitation given by the legislature to all persons, though students only of a day's standing, who are members of an inn of court, to take out licences to practise as special pleaders, &c., the benchers or governing members of some of the inns of court now require that upon the admission of a student, he shall engage not to practise as a special pleader, &c., till he be of sufficient standing to be called to the bar.

The serjeants remained however, till 9 & 10 Vict. c. 54, the only advocates recognised in the court of Common Pleas. In that court they retained their right of exclusive audience, which privilege extended to trials at bar, but not to trials at nisi prius, either at the assizes or at the sittings in London and Middlesex.

Attempts had been made previously to place the court of Common Pleas upon the same footing in this respect as the other courts at Westminster. A suggestion to that effect was made by Sir Matthew Hale, in his 'Considerations touching the Amendments of the Law.' In 1755 it was proposed by Sir John Willes, then chief-justice of the Common Pleas, that the court should be opened to all barristers. The judges met, and, after much discussion, expressed their opinion against the plan, which was strongly opposed by Lord Hardwicke. It was nearly a century before effect was given to the enlightened views of Sir Matthew Hale and Sir John Willes.

In 1834, while the Central Criminal Court bill was in the House of Lords, a clause was introduced for opening the court of Common Pleas. This clause was withdrawn before the bill was sent to the Commons. But on 24th April, in that year, a royal warrant issued, ordering and directing that the right of practising, pleading, and audience in the court of Common Pleas should cease to be exercised exclusively by the serjeants-at-law, and that barristers-at-law should have and exercise equal right and privilege with them of practising, &c., in that court. The warrant professed to give to such of the serjeants then in practice as were not king's serjeants, and had not patents of precedence, *as an especial mark of royal favour*, precedence over any king's counsel who might be thereafter appointed. This warrant was filed in the court of Common Pleas on 25th April, from which time until January, 1840, it was acted upon by the court. During this period no persons applied for the coif, except those who had received an intimation that they were to be made judges.

In 1837, a petition was addressed to her majesty by the queen's serjeants and two other serjeants who had not availed themselves of the clause of precedence contained in the warrant of April 24, 1834, suggesting that the warrant was illegal, and praying that the legality of that document and the expediency of the alteration might be duly investigated. The illegality of the warrant was asserted chiefly upon the prescriptive rights of the serjeants, coeval with the existence of the courts themselves; but also on some merely technical grounds. A memorial was at the same time presented to the chancellor, in which it was submitted that such an alteration could only be made by act of parliament.

The petition being referred to the privy council, the question was argued on 10th January, 1839, and again on 2nd February. A strong opinion was expressed as to the illegality of the warrant, but the court separated without coming to any conclusion.

In November, 1839, a motion was made in the Common Pleas by Wilde, as the senior practising serjeant, that the exclusive right of audience of the serjeants-at-law, which had been suspended in obedience to the warrant of 1834, should be restored; and at the close of Hilary term, 1840, the right of being heard as counsel and of signing pleadings in causes depending in the Common Pleas, was declared by the court to belong exclusively to the serjeants-at-law. The legislature then took up the question seriously, and the monopoly of the serjeants was abolished by 9 & 10 Vict. c. 54.

Serjeants had formerly not only *exclusive audience* in the Common Pleas, but had also in all other courts *pre-audience* over all other advocates. They are still addressed by the judges as brothers, by which title they speak to and of one another.

Though the king was represented in each of his courts at Westminster by one or more persons as his attorney and solicitor-general in one or all of those courts, no one formerly pleaded as *counsel* for the crown except serjeants. In the patent of a king's serjeant, he was appointed by the king "Serviens Noster ad legem, et Narrator pro Nobis in curiis Nostris, in quibuscunque negotiis Nos tangentibus." Afterwards when the king's attorney, as it usually happened, was an apprentice, he was allowed not only to appear as attorney, but to plead as advocate for the crown in those courts in which apprentices were permitted to practise, and when so employed he claimed and exercised, for the benefit of the crown, a right of pre-audience over serjeants pleading for ordinary clients in those courts. Afterwards the attorney-general exercised a right of pre-audience even when not engaged for the crown.

Other king's counsel appear to have obtained pre-audience over the serjeants by a similar course of proceeding; but the queen's serjeants still retain pre-audience over all other counsel except the attorney-general and solicitor-general; and even over the attorney-general, the senior of the king's serjeants, distinguished by the appellation of "the king's ancient serjeant," retained his precedence until 1814, when Sir Samuel Shepherd, the king's ancient serjeant, being appointed solicitor-general, instead of vacating his office of serjeant, as had always before been done in such cases, obtained a warrant from the Prince-Regent giving to the attorney-general and solicitor-general perpetual pre-audience of the whole bar. In the reigns of Mary, Elizabeth, and James I., several persons were degraded, or discharged, from the degree of serjeant-at-law in order to capacitate them for accepting the office of solicitor-general, as it is not unusual now for barristers to apply to be disbarred for the purpose of enabling them to practise as solicitors or attorneys to private suitors.

The pre-audience acquired, in comparatively modern times, by the attorney-general and solicitor-general and the other king's counsel over the serjeants in the courts of Westminster Hall, has not otherwise affected the rank or position of the latter. At the coronation of Queen Elizabeth it appears to have been finally settled that in the royal procession (in which those of inferior rank walk first) "the attorney and solicitor-general walk immediately before the barons of the Exchequer, and immediately after the serjeants-at-law, who follow the knights-bannerets, bachelor-knights, masters of the chancery, clerks of the court, &c." (Egerton 'Papers,' 60.)

The serjeants formerly occupied three inns, or collegiate buildings, for practice, and for occasional residence, situate in Chancery Lane, Fleet Street, and Holborn. The last, called Scroop's Inn, has long been abandoned, and since the burning down of Serjeants' Inn, Fleet Street, in the middle of the last century, that site has also been deserted by the serjeants, who have now no other building than Serjeants' Inn, Chancery Lane. Here all the common-law judges have chambers, in which they dispose in a summary way, and with closed doors, of such matters as the legislature has expressly entrusted to a single judge, and of all business which is not thought of sufficient magnitude to be brought before more than one judge, or which is supposed to be of a nature too urgent to admit of postponement.

The inn contains, besides accommodations for the judges, chambers for fourteen serjeants, the junior serjeants while waiting for a vacancy being dispersed in the different inns of courts.

In Serjeants' Inn Hall the judges and serjeants, as members of the Society of Serjeants' Inn, dine together during term-time.

Formerly very splendid and expensive entertainments were given by the new serjeants upon their reception into the order. About a century ago this custom was discontinued, and instead of festivities at their joint expense, each serjeant paid 100*l.* to the Treasurer of the Society of Serjeants' Inn upon his admission as a member of that Society, into which the new serjeants are elected almost as a matter of course. The payment is now raised to 350*l.* The practice of giving gold rings to the queen and the great officers of state and others still continues, though the number has been lately reduced. These rings, with the robes and other expenses, raise the 350*l.* to something less than 500*l.* The peculiar dress of the serjeants-at-law, besides their distinctive coif, consists in four species of robes. In term time the gown of black cloth is worn on ordinary occasions. On holidays the serjeants appear in court in purple (violet coloured) gowns. When they go in state to St. Paul's, they wear scarlet gowns, as also when they attend the House of Lords, if the sovereign be present, and when they dine at Guildhall on lord mayor's day. At nisi prius they appear in black silk gowns, which, as being at hand, they generally wear when called upon to try causes or prisoners on the circuit, though for the latter purpose the scarlet gown, always accompanied with a *sentence cap*, is understood to be the appropriate costume.

The creation of serjeants was anciently attended with numerous ceremonies, a description of which may be seen in the last chapter of Herbert's 'History of Inns of Court.' Some practices belonging to an age of greater simplicity than the present, are still retained in those cases where the writ to the serjeant elect issues *in term-time*. But by 6 Geo. IV., cap. 95, persons receiving writs, issued *in vacation*, commanding them to appear in the Court of Chancery and to take upon themselves the estate and dignity of a serjeant-at-law, are, upon appearing before the lord chancellor and taking the oaths usually administered to persons called to that degree and office, declared to be serjeants-at-law sworn, without any further ceremony.

Another class of serjeants is that of serjeants-at-arms, whose number is limited, by statute 13 Rich. II., cap. 6, to thirty. Their office is to attend the person of the king, to arrest offenders, and to attend the lord high steward when sitting in judgment upon a peer. Two of these serjeants-at-arms by the king's permission attend the two houses of parliament. In the House of Commons, the office of the serjeant-at-arms (as he is emphatically called) is to keep the doors of the house, and to execute such commands, especially touching the apprehension of any offenders against the privileges of the Commons, as the house through its Speaker may enjoin. From these serjeants-at-arms the present regimental serjeants are probably derived.

In some offices about the royal person the principal officer of the department is distinguished by the appellation of serjeant, as the serjeant-surgeon, serjeant-painter, &c.

Many of the documents referred to in the present article are printed at length in the Appendix to Manning's 'Serviens ad Legem,' which is a report of the argument before the Privy Council in 1839.

Serjeants and other counsel are engaged to assist a party in a cause either by the delivery of a brief in that cause or by giving a retainer or retaining fee. A retainer, if for a particular cause, or for a particular stage of that cause, is called a common retainer, and it now consists in the payment of the sum of one guinea and the delivering of a paper endorsed with the name of the cause and of the court, and the words "Mr. Serjeant A (or 'Mr. B'), retainer for the plaintiff" (or for the defendant). A general retainer is where a retaining fee of five guineas is given to counsel to engage the assistance of that counsel in all causes in which the party retaining may be concerned in the courts which the counsel retained attends. A special retainer is where a large fee is given to counsel to plead in a particular cause on a circuit on which he does not usually practise. This fee is given and received partly with a view to remunerate the counsel for the inconvenience of leaving other engagements to come to a strange circuit, and partly for the purpose of preventing any unnecessary interference with the business of the regular practitioners of the particular court into which he is brought, in cases which are not of great importance. Both the common and the special retainer amount to an engagement on the part of the counsel to accept the brief of the party retaining, and to refuse any brief offered by the adverse party, and on the part of the client, to deliver a brief to the counsel retained in case the cause is entered for trial, whether a trial takes place or not. A general retainer merely renders it imperative on the counsel retained to accept no brief or retainer from the adversary of the party retaining, until he has first ascertained that it is not the intention of the latter to require his services in the particular cause. The general retainer continues in force during the joint lives of the retaining client and the counsel retained, unless the engagement be cancelled by the former, who is at liberty at any time to renounce his title to the services of the counsel retained. In the case of a common or a special retainer, the contract can be put an end to only by the concurrent act of counsel and client.

In cases of importance, counsel are generally retained before the action is actually commenced; and it often happens that for want of sufficient information as to the form of the intended proceedings, or from carelessness, the cause is not described in the retainer with sufficient accuracy. When this is the case, the retainer is void, and the counsel is bound to accept the retainer of the adverse party, if tendered before the mistake has been corrected. The sufficiency of the first retainer becomes frequently the subject of dispute between the litigant parties, which dispute, if not arranged between themselves, is generally settled not by the counsel to whom the retainer is given, but by some other leading counsel.

In former times it was usual, particularly for great persons and public bodies, especially for religious corporations, to grant annuities pro consilio impenso vel impendendo.

SERJEANT, or SERGEANT, is a non-commissioned officer in a troop of cavalry or in a company of infantry. The duties of serjeants are to drill or instruct in discipline the recruits of a regiment; to look after the interior economy and discipline of the troop or company under the captain and subalterns; whilst on parade they act as markers or guides in the performance of the evolutions. The serjeants of infantry are now armed with muskets like the rest of the troops. In each company, when a battalion is in line, a covering serjeant is always stationed behind the officer commanding the company; when the ranks take open order, and that officer advances before the front rank, the serjeant steps into his place; but upon the ranks being closed, he falls again to the rear. Four or six serjeants are charged with the duty of guarding the colours of the regiment: they constantly attend the officers who carry them, and are called colour-serjeants. One serjeant in each troop or company is appointed to pay the men; also to keep the accounts relating to their allowances, the state of their necessaries, &c. There are five serjeants, including the colour-serjeant, to each company.

The name of sergens or servientes was, in the armies of France during the reign of Philip Augustus, applied to gentlemen who served on horseback, but were below the rank of knights; and also, as a general term, to the infantry soldiers who were furnished by the towns. There was, besides, a body of troops consisting of 150 or 200 men of rank, who were called sergens d'armes, and were instituted by the prince just mentioned for his protection, when in the East, against the subjects of the chief of the Assassins. (P. Daniel, 'Hist. de la Milice Fr.,' liv. iii. ch. 7, and liv. ix. ch. 12.)

Corresponding to this corps was the body of serjeants-at-arms, which was instituted in England by Richard I., and appointed to guard the royal tent in complete armour. At first it consisted of twenty-four men, but the number was afterwards increased. Being accused of extortion and oppression, the parliament made several applications to the king that their number might be diminished, and in the reign of Edward IV. the desired reduction took place. (Grose, 'Mil. Antiq.,' vol. i. p. 199.)

In the reign of Philip and Mary the serjeant-major of the army was an officer whose post corresponded to that of the modern major-general; and the serjeant-major of a regiment was a field-officer, who would now be designated the major. At present the serjeant-major is an assistant to the adjutant, and keeps the roster for the duties of the serjeants, corporals, and privates. The quartermaster-serjeant is one who acts immediately under the quartermaster of a regiment in all the details relating to the quarters of the officers and men, the supplies of food, clothing, &c.

SERJEANT-AT-ARMS. [SERJEANT. (Law.)]
SERJEANT-AT-MACE. [SERJEANT. (Law.)]
SERJEANTY. [SERJEANT. (Law.)]

SERMON, a form of the Latin *sermo*, which denotes a discourse of any kind, and even common talk or conversation. It is now however applied only to a discourse of a particular kind, namely, one delivered to an assembly of persons who are gathered together for purposes of devotion, or in the character of a Christian and religious congregation. Nor is any address delivered on such occasions properly a sermon, though the word is very loosely used, and addresses delivered on such occasions, which can hardly be called sermons, are not unfrequently so denominated; but it seems to be essential to a sermon that it shall be a discourse grounded on some particular passage of holy Scripture which more or less influences the preacher in the whole of his discourse. This passage is called the *text*, that is, it is the portion of the *text of Scripture*, of which the sermon is the long paraphrase and commentary, with suitable application and exhortation intermixed or appended.

The sermons delivered in the English church before the Reformation were very short, probably seldom requiring more than ten minutes for the delivery of them. Many specimens remain in manuscript, but few are generally accessible by having been printed. Perhaps the most remarkable and the most easily consulted are the sermons at the opening of each parliament, of which there are notices in the printed rolls.

But with the Reformation a great change in this respect took place; and in many cases the ministers of religion came to consider themselves rather as persons whose peculiar duty it was to exhort and preach, than to conduct the devotions of a Christian assembly and to minister the sacraments. The consequence of this was that the sermons ran out to a great length, and assemblies were gathered together rather for the purpose of listening to them than of entering into the devotions of the church; and the term "preaching minister" was invented to designate those ministers who changed the nature of their office, from one which was instituted for the administration of the

Christian ordinance and the assisting the people in their devotions, to one which was of teaching, if not exclusively, yet principally. It was not very unusual in the 17th century for congregations to listen to sermons which occupied one, two, or even three hours in the delivery. Many of these sermons are in print, and may therefore be now read and judged of.

There is a singular work by a minister of the French Reformed church at Charenton, Monsieur Claude, entitled 'An Essay on the Composition of a Sermon.' This was translated by Robert Robinson, a Baptist minister at Cambridge, who has illustrated the rules by numerous quotations from English sermon writers. This translation is in two volumes, 8vo., 1779.

SERPENS (the Serpent), a constellation which is astronomically distinguished from OPHIUCHUS, but not mythologically, being the serpent carried by the Serpent-bearer. The windings of the figure bring it in contact with Aquila, Ophiuchus, Libra, and Hercules.

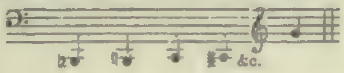
SERPENT, a musical instrument, a long conical tube of wood covered with leather, having a mouth-piece, ventages, and keys, and bent in a serpentine form; hence its name. The compass of the serpent is from B flat below the base staff, to G, the treble clef line, including every tone and semitone between these extremes. Or—



The use of this is confined to military bands, though it might have been rendered valuable in the orchestra. The ophecleide however, an instrument applicable to the same purposes, but of far superior utility, has already obtained a place in the concert-room, and will, probably, supersede altogether its ancient and imperfect precursor. [OPHICLEIDE.]

SERPENTARIN. Synonymous with ARISTOLOCHIN.

SERVANT, one who has contracted to serve another. The person whom he has contracted to serve is styled master. Servants are of various kinds; apprentices [APPRENTICE], menial or domestic servants who reside within the house of the master, servants in husbandry, workmen or artificers, and clerks, warehousemen, &c. From the relation of master and servant a variety of rights and duties arise. Some of these are founded on the common law, and some on special statutory enactments.

A contract of hiring and service need not be in writing unless it be for a period longer than a year, or for a year to commence at some future time. If in writing, it is not liable to any stamp duty, unless it apply to the superior classes of clerks, &c. To all such contracts the law attaches an implied undertaking on the part of the servant faithfully and carefully to serve the master, and to do his lawful and reasonable commands within the scope of the employment contracted for; on the part of the master, to protect and fairly remunerate the servant. This implied undertaking to remunerate may be rebutted by circumstances showing that it never was contemplated, as where it appears that the servant merely came on trial, or where a party has brought to England a person who was his slave abroad. In all hirings where no time of duration is expressed, except those of menial servants, it is a rule of law that the contract shall continue for a year. In the case of menial servants it is determinable by a month's warning, or the payment of a month's wages. Servants in husbandry can only be discharged or quit the service upon a quarter's notice. This rule as to time may of course also be rebutted by any circumstances in the contract inconsistent with its existence. In the case of immorality, or any kind of offence amounting to a misdemeanor committed during the time of the service, or of continued neglect, or determined disobedience, a servant may be immediately discharged; and the service having been determined before the expiration of the time contracted for, in consequence of the fault of the servant, he is not entitled to claim wages for any portion of the time during which he has served. The contract continues to exist, notwithstanding the disability of the servant to perform his duties from illness, and he is in such a case entitled to receive his wages. The master however is not bound to pay the charges incurred by medicine or attendance upon his sick servant. In case the goods of the master are lost or broken by the carelessness of the servant, the master is not entitled to deduct their value from the wages of the servant, unless there has been a special contract between them to that effect. His only remedy is by an action. Where a master becomes bankrupt, the commissioners are authorised, on proof that they are due, to pay six months' wages to his clerks and servants. If the wages for any longer period are due, they must be proved for like other debts under the fiat. If a servant has left his service for a considerable time without making any demand for wages, it will be presumed that they are paid. A master may chastise his apprentice for neglect or misconduct, but he will not be justified in striking any other description of servant. Servants who steal or embezzle their master's goods are subject to a greater degree of punishment than others who commit those crimes. [LARCENY.] Masters are not compellable to give a character to servants who leave their employment. If they choose to do so, and they give one which is false, they may be liable to an action at the suit of the servant; but in order to recover in such an action, the servant must prove that the character was maliciously given for the purpose of injuring him. If the master, merely for the purpose of confidentially communicating, *bonâ fide* state what he believes to be the truth respecting a servant, he is not responsible for the consequences of his communication.

By a great variety of statutes, a special jurisdiction is given to magistrates over servants in husbandry, and also in many classes of manufactures and other employments. None of these rules of law apply to menial servants. The object of them, as relates to servants in husbandry, is to compel persons not having any ostensible means of subsistence, to enter into service, to regulate the time and mode of their service, to punish negligence and refusal to serve, to determine disputes between masters and servants, to enable servants to recover their wages, and to authorise magistrates under certain circumstances to put an end to the service.

Those statutes which relate to servants in manufactures and other employments prohibit the payment of wages in goods, and provide for their payment in money, and for the regulation of disputes concerning them. They also contain various enactments applicable to the cases of workmen, &c., absconding, neglecting or mismanaging their work, injuring or embezzling the materials, tools, &c., entrusted to them, and fraudulently receiving those entrusted to others. With respect also to this class of servants, magistrates have authority to put an end to the contracts of hiring and service.

By reason of the relationship which exists between a master and a servant, and the protection which is thereby due from the former to the latter, a master is not held to be guilty of the offence of maintenance [MAINTENANCE], though he maintain and support his servant in an action brought by him against a third party. When a servant is assaulted, his master is justified in assisting his servant, and repelling the assault by force, although he himself be not attacked; and under similar circumstances a servant may justify an assault committed in defence of his master. A master is answerable, both civilly and criminally, for those acts of his servant which are done within the scope of his employment. Thus a master is indictable if a servant commit a nuisance by throwing dirt on the highway; and a bookseller or newsvender is liable, criminally as well as civilly, for libels which are sold by his servant in his shop. This liability of the master does not release the servant from his own liability to punishment for the same offence. The servant is also liable when he commits a trespass by the command of his master. A master, although liable civilly for any injuries arising from the negligence or unskilfulness of his servant, is not responsible for the consequences of a wilful act of his servant done without the direction or assent of the master: in such case the servant alone is liable. Where a servant makes a contract within the scope of his employment, what he does will be binding on his master, just as if he had expressly authorised the servant. But in all cases where there is no express evidence of the delegation of the master's authority, there must be facts from which such delegation can be inferred. Where a servant obtains goods for his master, which the master uses, and he afterwards gives money to the servant to pay for them, the master will be liable to pay for them, even though the money should have been embezzled by the servant. If a coachman go in his master's livery to hire horses, which his master afterwards uses, the master will be liable to pay for them, though the coachman has received a large salary for the express purpose of providing horses; unless, indeed, that fact were known to the party who let out the horses. If a master is in the habit of paying ready money for articles furnished to his family, and gives money to a servant, on a particular occasion, for the purpose of paying for the articles which he is sent to procure, the master will not be liable to the tradesman if the servant should embezzle the money. Where articles furnished to a certain amount have always been paid for in ready money, and a tradesman allows other articles of the same character to be delivered without payment, the master will not be liable, unless the tradesman ascertains that the articles are for the master's own use. Where a tradesman, who had not before been employed by a master, was directed by a servant to do some work, and afterwards did it without any communication with the master, it was held that the master was not liable, though the thing upon which the work was done was the property of the master.

By the contract of hiring and service, the master obtains a right to the service of the servant. Any one, therefore, who interferes with that right does him an injury for which he is responsible in an action for damages. A master may be deprived of the services of a servant, either by some hurt done to the servant, or by his being enticed out of the service. An action, therefore, may be brought by a master where a servant has received some personal injury disqualifying him from the discharge of his duties as a servant, as where he has been disabled by the overturn of a coach, the bite of a third person's dog, &c. The action by a parent against the seducer of his daughter is of this class, and purports to be brought to recover the damages incurred by the parent for the loss of his daughter's services; and although in practice the damages are never really measured by the injury occurring from the mere loss of service, still, from the form of the action,—the only one which can be brought in such a case,—it is necessary to give evidence of services performed. Any kind of assistance in domestic offices is sufficient. [PARENT AND CHILD.]

In order to succeed in an action for enticing a servant out of his service, the master must prove that the party enticing away the servant knew of the previous engagement at the time when he enticed him away, or that he has refused to restore the servant upon subsequent application. This action is maintainable where the servant is hired to do work by the piece, as well as where the servant is hired for a definite time. But no action lies for inducing a servant to quit his service at the period when the definite time for which he was hired expires, although the servant had no previous intention of quitting the service at such period. Neither will an action lie against a party for enticing away a servant if the servant has paid to the master the penalty stipulated for by the agreement of hiring and service in case of his quitting his master's service. Where a servant has been enticed away from the service, an action lies against him for his breach of contract, as well as against the party who has enticed him away.

It is not inconsistent with the duty of the servant of a tradesman to solicit his master's customers to give him business after he shall have left the service of his master. Where a workman discovers a new invention during the time of his service, the invention is the property of the servant, unless perhaps he were specially hired for the purpose of making new inventions.

Penalties are imposed by the statute law upon parties who personate masters and give false characters with servants; and also upon those who, though they really have been masters, wilfully make false statements in writing, as to the time and particulars of the service or the character of the servant, and also upon those who personate servants or falsely state that they have been in particular services, or deny that they have been in such employments as they really have filled. A person who wilfully gives a false character with a servant is also liable to an action at the suit of the party who has been induced by the false character to employ the servant, for any damages which he may suffer in consequence of employing him. Thus, where one was induced by a false character to employ a servant who afterwards robbed him to a large amount, and was convicted of the robbery, the master was held to be entitled to recover to the extent of his loss from the party who gave the false character.

Formerly a settlement was gained by residence in a parish under a contract of hiring and service for a year; but no settlement can now be gained by such means.

SERVICE (Law). [SERVANT.]

SERVICE, the name given in English cathedral music to the *Te Deum* and *Jubilate*, the *Magnificat* and *Nunc Dimittis*, the *Cantate Domino* and *Deus Misereatur*, collectively or separately; and sometimes applied, very erroneously, in our concert books, to the whole or portions of the mass.

SERVITES, or Servants of the Blessed Virgin, a religious order first instituted in Tuscany, A.D. 1233, by seven Florentine merchants. This order, though subjected to the rule of St. Augustine, was nevertheless erected in commemoration of the most holy widowhood of the blessed Virgin, for which reason its monks wore a black habit, and observed several rules not practised in other monasteries.

Toward the close of the 16th century it was found that the Servites had fallen off from their early strictness; and in 1593 the order was re-established in its original austerity in the hermitages of Monte-Senario, where the reformed brothers took the title of *Servites-Eremites*. This order continues to exist in Italy.

Father Paul Sarpi, the well-known author of the 'History of the Council of Trent,' was a Servite.

(Mosheim, *Eccles. Hist.*, Cent. xiii. Part ii. s. 20; *Hist. des Ordres Religieux*, par M. Henrion, 8vo. Brux., 1838.)

SERVITOR. [SIZAR.]

SERVITUDE, PENAL. [PENAL SERVITUDE.]

SERVITUDES (*servitutes*). A servitus in the Roman law signifies that the owner of some particular property is bound in respect to some other person, simply as such person, or as being the owner of a particular property, either not to do certain acts to his property, or to allow that other person to do some particular acts to the property.

Servitutes were thus either a right belonging to some particular person, which ceased with his life (unless they were granted to him and his heirs), and were called servitutes personarum or personales; or they were attached to a piece of ground as the subject, and could be exercised by any person who was in the possession of the ground, and were called Jura, or servitutes prædiorum or rerum, and sometimes Servitutes simply. Personal servitudes were comprehended under the heads of Ususfructus, Usus, Habitatio (a lodging in another person's house), and Operæ Servorum et Animalium (the use of another person's slaves or beasts).

Prædial Servitudes were either Servitutes Urbanæ or Rusticæ. They were Urbanæ if the property which was entitled to the servitude was a building; they were Rusticæ if it was a piece of ground. There was no limit to the number or kind of servitudes of this class which might be established. Those Servitutes Urbanæ which were of ordinary occurrence were such as follow:—Servitutes oneris ferendi, the right which a man has to let his building rest on the building, the wall, or the pillar which belongs to another; Tigni immittendi, the right of fixing a man's timbers in his neighbour's wall; Luminum, sive luminis excipiendi, the right of a man's making windows or openings in his neighbour's wall, or in a common wall, in order to get light for his own building, or to make holes or windows in a man's own wall, which holes or windows look into his neighbour's property, in such cases as would be unlawful without the existence of the servitude; Ne luminibus officiatur, the right to prevent a neighbour from obstructing the light that comes to a man's buildings, by raising any obstacle in the way; and others of a like kind. The Servitutes Rusticæ were rights of road over another man's property, which were of various kinds according to the kind of road, as Servitus itineris, actus, viæ; Pascendi sive pascui, right of pasturing a man's animals on another man's ground; and the various servitudes which have for their object the use of water, as servitus aquæ ductus, aquæ haustus, and others of a like kind.

Servitudes might be established by contract, by testamentary disposition, by prescription in the Roman sense, and in some other ways. They might cease by the party entitled to them renouncing them by express words or tacitly: in the case of prædial servitude, by one person becoming owner of the servient and dominant properties; and in some other ways.

The prædial servitudes may be compared with some of the easements and rights of the English system. The personal servitudes of the Roman law do not correspond, except in some few cases, with anything in the English law, except limited enjoyments of a thing, as, for instance, an estate in lands for life.

The subject of the Roman servitudes would require a long exposition to be treated fully. A good outline is contained in Thibaut, 'System des Pandekten Rechts,' i. § 296, &c., 9th ed.; and in Mackeldey, 'Lehrbuch,' &c., ii. § 274, 12th ed.

SESQUIALTER, the name of a stop on the organ, containing three ranks of pipes, thus giving three pipes to each organ key, which are tuned in different but harmonic intervals. Sometimes the *Mixture* stop is considered as part of the Sesquialter, in which case the latter is said to contain five ranks of pipes, all tuned in harmonic intervals. [ORGAN.]

SESSION, COURT OF, is the principal tribunal of civil jurisdiction in Scotland. As at present constituted, it dates back to the year 1532, but it was then reconstructed on the basis of institutions which had existed at a much earlier period. The early records of the Scottish Parliament show that the judicial authority, which in those times was mixed with the legislative functions of that body, was often deputed to committees. These were termed Domini Auditores, or Domini ad Querelas, and received other like titles. We find these committees and their functions placed on a more distinct position in 1503, when a permanent body received the designation of "The Daily Council." It is worthy of observation that these incidents in the history of the court explain the absence of jury trial as a fundamental feature in the Court of Session, while in early times it is known to have belonged to the courts of the inferior judges. Parliament being the high jury of the nation, it would be an anomaly that a committee of that body should act through the aid of a jury. The number of the court as finally established in 1532 was fifteen, the usual number of a Scottish jury in former times, and still the number of a jury in a criminal prosecution. There was then a lord chancellor of Scotland, whose functions in some degree resembled those of the same official in England. He presided over the Court of Session, and his judicial functions gradually came to be absorbed in those of the court. At the union with England it was deemed unnecessary to retain a separate chancellor of Scotland, and the great seal to be appended to private documents for that part of the country being committed to a keeper, the court was presided over by the lord president, who previously presided in the absence of the chancellor. In 1808 the Court of Session was divided into two divisions: the head of the court, the lord president (who is also now lord justice-general or head of the supreme criminal court) presides in the first division, and the lord justice clerk in the second. In 1815 trial by jury in civil cases was introduced in Scotland, a separate tribunal being established for these cases; but in 1830 the practice of jury trial was united with that of the Court of Session. It is still only adopted in a limited number of cases, and is far from being popular or satisfactory. The Scottish mode of pleading is ill adapted to it, and no means have been found, or indeed tried, of carrying it through with the promptitude and precision which mark the English practice. In 1830 two separate courts of limited jurisdiction and small practice—the Admiralty and Commissionary Courts—were absorbed in the Court of Session, and the number of judges was at the same time reduced from fifteen to thirteen. Eight of these judges, formed into two courts of four judges each, sit in the two divisions of the Inner House, where each division forms a court of second instance. The five other judges are called the Lords Ordinary, and each of them holds a separate court, which, in reference to the court of further resort, is called the "Outer House." The judgment of a lord ordinary on a closed record is final in the Outer House, but it may, within a limited time, be carried by a "reclaiming note" to which the record is appended, to the Inner House, where it may be pleaded again on the record as made up in the Outer House.

The jurisdiction of the Court of Session embraces all questions of civil right. It gives remedy when other courts whose function it is to regulate the rights and duties of certain sections of the public as members of a particular class—such as courts martial and ecclesiastical—exceed their powers. The proceedings before the Court of Session in relation to the church courts were the cause of the great secession from the Scottish Church in 1843. As every description of civil question between man and man in Scotland can be competently decided before the Court of Session, it is usual in England to speak of it as a court "both of law and equity;" but this is a distinction proceeding from incidental circumstances in the character of the English courts, and is no necessary or properly systematic division of the administration of the law. The Court of Session has the authority enjoyed by the equity courts in England, in the appointment of guardians, receivers, &c., or otherwise seeing to the protection of property, or of persons where discretional protection or direction are necessary, and there is no person competent in ordinary course of law to act. It has also the same authority as the Court of Exchequer in matters of revenue. By an old practice in Scotland, each "Senator of the College of Justice," as the judges of the Court of Session are officially called, takes the title of lord.

SESSION, KIRK, is the lowest judicatory in the system of the Church of Scotland, having jurisdiction only over a single parish. There is, or ought to be, a kirk session in every parish, composed of the minister, who is *ex officio* moderator or chairman, and of the lay elders, who must be at the least two in number. The moderator has only a casting vote. Meetings of the kirk session may be called at any time by the minister; but they are commonly held at stated intervals, and it is not unusual for the session to meet on the Sunday after service. It would rather appear from the 'First Book of Discipline' that the nomination or election of elders was originally in the congregation; but the modern practice is for the session to supply vacancies in, and to make additions to, its number by its own selection, only submitting the names to the congregation, that any objections may be made and inquired into by it; and in cases where there happens to be no session in existence, one is appointed by the presbytery. In some of the largest town parishes there are as many as fifty or sixty elders; but in most cases the number does not exceed five or six. In country parishes the elders, or at least those of them who do the duties of the office, are commonly respectable tradesmen, shopkeepers, or mechanics, although persons of higher station occasionally get themselves appointed, principally with a view to qualifying themselves for seats in the General Assembly or the other church courts. The law however is, that an elder must be resident in the parish at least six weeks in the year. He is elected for life, or so long as he remains qualified to hold the office. Every kirk session is represented by an elder both in the presbytery and the synod; the same member being deputed to both courts, and holding his commission for six months. The elders sent to the Assembly, like the other members of that supreme court (except the representatives of the royal burghs and the universities), are nominated by the presbytery. The kirk session may be regarded as the council of the minister, who, strictly speaking, is scarcely authorised to perform any act in the administration of the spiritual affairs of the parish, beyond officiating in the services of the kirk, without the concurrence of his elders. In practice, however, the clergyman very rarely encounters any opposition in the kirk session. The ordinary business of the session is to exercise spiritual discipline within the parish, by inquiring into scandals, and punishing delinquencies, which is done by suspension from the benefit of church ordinances, by public or private rebuke, and by pecuniary fines (exacted of course, like submission to the other penalties, only as the price of restoration to communion with the church, for the session has no power to force any person even to appear on its summons). The evidence in all cases that come before the session (at least after the inquiry has fairly commenced) is taken upon oath, and is, or ought to be, carefully recorded by the session-clerk, who is a paid officer, not necessarily a member of the court. There is in most cases an appeal from the judgment of the kirk session to the presbytery; and some graver offences can only be tried by the presbytery even in the first instance. The distribution of the ordinary collections made at the church door for the support of the poor, is also in the hands of the kirk session; and the management of all other funds and assessments allotted to the same purpose is conjointly in that body and in the heritors or landed proprietors of the parish. In the non-established Presbyterian bodies the lay-members of the kirk-session are appointed by the direct vote, or with the consent of the members of the congregation. The duty of the session, of which the minister is moderator, is to attend to the spiritual discipline of the body, and to care for the

poor. A body of *managers* is generally chosen at an annual business meeting of the members of the congregation, whose duty is to transact the secular business, such as collecting seat-rents, paying the minister's stipend, &c. In the Free Church of Scotland, *deacons* are usually appointed, who in conjunction with the elders, constitute the *deacons' court* , for the management of the secular affairs of the congregation.

(Principal Hill's *View of the Constitution of the Church of Scotland*; Dr. Alexander Hill's *Practice in the several Judicatories of the Church of Scotland.*)

SESSIONS. A session is the period during which any court of law sits for the transaction of judicial business; but the term Sessions is commonly used to denote the meeting of the justices of a county, or other district which has a separate commission of the peace, for the execution of the authorities conferred by the crown by that commission and others created by act of parliament.

County Sessions.—The commission of the peace issued by the crown for the purpose of creating county magistrates, consists of two branches. The former, relating to the powers to be exercised by justices individually and separately, has been already set forth. [JUSTICES.] The second branch of the commission creates the powers of the justices when assembled in sessions, and contains the quorum clause, so called because when the commission was in Latin, the clause ran "*quorum* A.B. vel C.D. vel E. F., &c. unum esse volumus."

The statute 1 Mary, sess. 2, c. 8, s. 2, prohibits sheriffs from exercising the office of justice of the peace during the time that they act as sheriffs. They might otherwise be called upon to act in the same matter both as judges and officers,—to execute, as sheriffs, precepts which they had issued as justices. It has been supposed that where a justice is elected coroner, he is discharged of his authority of justice. But if he be created a duke, archbishop, marquess, earl, viscount, baron, bishop, knight, judge, or serjeant-at-law, his authority as justice of the peace remains. (1 Edw. VI. c. 7.) By 5 Geo. II. c. 18, s. 2, attorneys, solicitors, and proctors are prohibited from acting as justices of the peace for any county during the time that they continue in practice.

A meeting of the justices held for the purpose of acting judicially for the whole district comprised within their commission constitutes a court of general session of the peace. By 12 Rich. II. c. 10, sessions are required to be held in every quarter of the year, or oftener if need be. The four sessions so held are styled courts of general quarter-session of the peace, or, in common parlance, "quarter-sessions." By different statutes the quarter-sessions are directed to be held at uniform periods. The times at which they are directed to be held are, the first week after the 11th of October, the first week after the 28th of December, the first week after the 31st of March, the first week after the 24th of June. Though the justices act irregularly in omitting to convene the quarter-sessions at the prescribed periods (except the April sessions, in respect of which power is expressly given to the justices to alter the time to any day between the 7th of March and the 22nd of April), sessions held as quarter-sessions in other periods of the quarter are legal quarter-sessions. When the business to be transacted at a court of quarter-sessions is not completed before the time at which it is thought desirable for the justices to separate, the court is usually adjourned to a subsequent day; so where there is reason to expect that new matters will arise which it will be desirable to dispose of before the next quarter-sessions. Two justices, one of them being of the quorum, may at any time convene a general session of the peace; but at such additional session no business can be transacted which is directed by any act of parliament to be transacted at quarter-sessions.

Both general sessions and general quarter-sessions are held by virtue of a precept under the hands of two justices, requiring the sheriff to return a grand jury before them and their fellow-justices at a day certain, not less than fifteen days after the date of the precept, at a certain place within the district to which the commission extends, and to summon all coroners, keepers of jails and houses of correction, high constables, and bailiffs of liberties [FRANCHISE] within the county.

Persons bound to attend at the sessions are, first, all justices of the peace for the county or district; secondly, the custos rotulorum of the county, who is bound to attend by himself or his deputy, with the rolls of the sessions; thirdly, the sheriff by himself or his under-sheriff, to return the precept and lists of persons liable to serve on the grand or petty jury, to execute process, &c.; fourthly, the several coroners of the county or district; fifthly, the constables of hundreds or high constables; sixthly, all bailiffs of hundreds and liberties; seventhly, the keepers of jails, to bring and receive prisoners; eighthly, the keeper of the house of correction, to give in a calendar and account of persons in his custody; ninthly, all persons returned by the sheriff as jurors; tenthly, all persons who have entered into a recognisance to answer charges to be made against them, or to prosecute or give evidence upon charges against others.

Persons summoned on grand or petty juries ought to be males between 21 and 60 years of age, who are possessed of 10*l*. a year in lands or rents, or 20*l*. a year in leaseholds for an unexpired term or terms of 21 years or more, or who are householders, rated to the poor on a value of not less than 20*l*. (in Middlesex 30*l*.), or who occupy houses containing not less than 15 windows, and who are not peers, judges of the superior courts, clergymen, Roman Catholic priests, dissenting ministers following no secular employment but that of schoolmaster, serjeants or barristers-at-law, doctors or advocates of civil law actually practising, officers of courts actually exercising the duties of their respective offices, coroners, jailers or keepers of houses of correction, members or licentiates of the College of Physicians actually practising, members of the Royal Colleges of Surgeons in London, Edinburgh, or Dublin, and actually practising, certificated apothecaries actually practising, officers in the army or navy in full pay, pilots licensed by the Trinity House, masters of vessels in the Buoy and Light service, pilots licensed by the lord warden of the Cinque Ports or under any act of parliament or charter, household servants of the crown, officers of the customs or excise, sheriffs' officers, high constables or parish clerks.

The justices in sessions have criminal jurisdiction, to be exercised partly according to the rules of common law and partly in a course prescribed by different acts of parliament; they have also jurisdiction in certain civil matters created by different statutes; they have an administrative power in certain county matters; and they have power to fine and imprison for contempt.

I. The criminal jurisdiction of justices in sessions, according to the course of common law, enabled them to try felonies and those misdemeanors which are not directed by any statute to be tried in a summary way. It has been said that they had no jurisdiction in cases of perjury and forgery; but this opinion seems to have arisen from the circumstance that at common law these crimes were only misdemeanors, and the authority of the justices extended only to such misdemeanors as were specially mentioned in their commission, or which came within the description of trespasses; and though most species of forgery have since been made felony, the opinion that courts of quarter-sessions had no jurisdiction in cases of forgery was commonly entertained.

The jurisdiction given by the commission of the peace, in respect of felonies, is expressed in very general terms, and in former times numerous executions for felony took place at the quarter-sessions. The practice during the present and the greater part of the last century was, however, not to try at the sessions persons charged with capital crimes, but to leave them for trial by the judges at the assizes. All questions of this description are, however, set at rest; for the criminal jurisdiction of justices in general and quarter-sessions is now defined by the 5 & 6 Vict. c. 38, which enacts "that after the passing of this Act neither the justices of the peace acting in and for any county, riding, division, or liberty, nor the recorder of any borough, shall at any session of the peace nor the adjournment thereof try any person or persons for any treason, murder, or capital felony, or for any felony which, when committed by a person not previously convicted of felony, is punishable by transportation beyond the seas for life," or for any of the offences mentioned under the 18 heads contained in the first section of the Act. The second section provides that any judge of the supreme courts at Westminster, acting under a commission of oyer and terminer and jail delivery for any county, may issue a writ or writs of certiorari or other process directed to the justices of the peace acting in and for such county, &c., or to the recorder of any court within the same county, commanding the said justices and recorder severally to certify and return into such court of oyer and terminer, &c., all indictments and presentments found or taken by such justices or recorder of offences which, after the passing of this Act, they will not have jurisdiction to try, and the several recognizances, examinations, and depositions relative to such indictments and presentments; and, if necessary, by writ or writs of Habeas Corpus, may cause any person in the custody of any jail or prison, charged with any such offence, to be removed into the custody of the common jail of the county, that such offences may be tried under the said commission.

Previous to the year 1836 it was in the discretion of the magistrate before whom the depositions were taken, whether he would allow them to be inspected; even the party accused had no right to demand a copy of the depositions, though in cases of treason or felony he was entitled to demand a list containing the names of the witnesses for the prosecution. But now all persons held to bail or committed to prison for any offence, may at any time after the completion of the examinations, and before the first day of the sessions (or assizes), require and have, from the person who has the custody thereof, copies of the examinations of the depositions on which they were held to bail or committed to prison, on payment of a reasonable sum for the same, not exceeding three-halfpence for each folio of ninety words. (See 11 & 12 Vict. c. 42, s. 27, substituted for the previous provisions of the 6 & 7 Wm. IV. c. 114.)

A prisoner or defendant charged with a felony or a misdemeanor, although entitled to defend himself by counsel, cannot have the assistance of counsel to examine the witnesses, and reserve to himself the right of addressing the jury. But if he conduct his defence himself, and any point of law arises which he professes himself unable to argue, the court will hear it argued by counsel on his behalf.

Where the quarter-sessions act as a court of criminal jurisdiction under the powers given by the commission, and according to the course of common law, a writ of error lies upon the judgment of the sessions to the court of Queen's Bench, and from that court to the Exchequer Chamber, and ultimately to the House of Lords. By the statute 11 & 12 Vict. c. 78, these courts, in common with the courts of Oyer and Terminer and Gaol Delivery, are empowered to reserve questions of law for the consideration of the court of Criminal Appeal; and by the statute 12 & 13 Vict. c. 45, the powers previously given to judges to order payments by way of reward for the apprehension of certain offenders was extended to these courts, the compensation to one person in no case to exceed 5*l.*

II. The quarter sessions have an original jurisdiction in all matters required to be done by two or more justices, except in cases in which a power is given of appealing to the sessions.

III. Statutes which give summary jurisdiction to one or more magistrates, in most cases allow their decision to be brought before the sessions by way of appeal. Notice of appeal is generally required, and the court is precluded from entertaining any objections not specified in the notice. Subject to this restriction, the case is heard as if the question were raised for the first time. Upon hearing of an appeal in which several counsel are employed, the course of practice usually is this:—the senior counsel for the respondent (the party resisting the appeal) states his case in accordance with the decision appealed against. The witnesses and documents in support of that case having been produced and examined, the senior counsel for the appellant addresses the court, and then his witnesses are examined. Both counsel for the appellant then address the court, and are followed by the counsel for the respondent; if no evidence is produced on the part of the appellant, the appellant's counsel sum up their case, and the respondent's follow. The practice in this respect, however, varies at different sessions. When the case is closed, the order, conviction, or other matter appealed against is confirmed or discharged, according to the view which the majority of the justices present at the moment of the decision take of the case, they being the judges in cases of appeal, both as to the law and the fact. Where, however, questions of difficulty in matter of law present themselves upon the hearing of an appeal, the party against whom the sessions decide frequently applies for leave to state a special case for the decision of the court of Queen's Bench: the majority of the justices may either grant or reject the application; and if no special case be stated, the judgment of the quarter-sessions upon an appeal, or upon any other matter in which they proceed in a course prescribed by statute, different from the course of the common law, cannot be reviewed by any other court. The stat. 12 & 13 Vict. c. 45, has amended the procedure in courts of quarter-sessions, by prescribing uniformity of time for giving notices of appeal; by conferring extensive powers of amendment; a large discretion as to costs; and by enabling them to refer matters to arbitration.

IV. The quarter-sessions have jurisdiction over the appropriation of the county stock, an annual fund raised principally by county rates. This part of the business of the court is usually disposed of before any other, and in practice the first day of the sessions is generally exclusively devoted to what is called "the county business."

V. In common with other courts of record, justices of the peace, whether assembled in sessions, or sitting as individual magistrates, may vindicate their authority by fining and imprisoning for contempt. No superior court can inquire into the existence or non-existence of the fact which has been so treated as a contempt, or into the reasonableness of the fine imposed or imprisonment awarded. The court of quarter-sessions has, however, no power of punishing contempts or other offences committed by one of their own body.

The justices being assembled in sessions elect a chairman. A panel, or list of persons returned to serve on the grand-jury, being called over, twenty-three, if so many appear, are sworn to inquire of the truth of the matters which will be brought before them, and not to disclose what is brought before them. If twenty-three do not appear, the court may proceed with a smaller number; but nothing can be done by the grand-jury without the concurrence of twelve of its members, and it is not usual to take less than thirteen, though twelve may be sworn, if, after waiting a reasonable time, more do not attend. Those persons in the panel who do not answer to their names are liable to be fined; and where it is thought desirable to ensure full attendance in future, the whole panel is called over for the purpose of discovering and punishing all the defaulters. The grand-jury being sworn, the royal proclamation against vice and immorality is read by the clerk of the peace. The chairman delivers his charge to the grand-jury, in which, as he is in possession of the depositions taken when the prisoners were committed, he calls their attention to such cases as appear to present any difficulty, and explains such points of law as are necessary for their guidance. The grand-jury then retire to their room to receive such bills of indictment as may be brought before them.

When the business of the sessions is such as to be likely to occupy a considerable time, it is usual to appoint a second chairman to preside in a separate court, under the authority of the 21 & 22 Vict. c. 73, substituted for previous provisions for the same purpose. The bills of indictment on parchment, with the names of the witnesses indorsed thereon, are taken to the grand-jury, who call in, swear, and examine the witnesses in succession, no other person being present. The examination being concluded, if a majority consisting of not less than twelve are of opinion that the charge is supported by the evidence, the bill of indictment is indorsed "a true bill," or the indorsement may state that the bill is true in such and such parts, and not true in others, or the grand jury may themselves strike out or alter any part of the bill, and return it in its corrected form as a true bill generally. If a majority of the grand-jury think that the party is not guilty, or if the number that think him guilty be less than twelve, they indorse "not a true bill;" though in the latter case the old form of indorsement, "ignoramus" (we do not know), seems to be more correct. It not unfrequently happens that grand-jurors return "a true bill" where the evidence which has been brought before them is such as merely to raise in their minds a strong suspicion of the guilt of the party accused, acting under an impression that it is not their duty to try the guilt of the party, and that the inquiry which has taken place in the grand-jury room is in the nature of a precognition little differing from the preliminary examination which takes place before a magistrate, who is bound to commit or to require bail if a probable cause of guilt be made out. By the common law of England, a man is not liable to punishment until the fact charged against him has been found to be true by the oath of twelve men (whether grand-jurors, leet-jurors, or jurors impanelled to try an issue in a civil cause involving a charge of crime), nor until such finding has been afterwards confirmed by the verdict of twelve others, forming the petty-jury, or by the confession of the party by pleading guilty in open court. The judgment of the court ought in strictness perhaps to be considered as founded upon the presentment of the grand-jury, and the proceedings which take place before the petty jury may be said to be less a trial of the guilt or innocence of the prisoner than a trial of the truth or falsehood of the indictment. The grand-jury are sworn to inquire, not whether the accused ought to be put upon his trial, but whether the matter in respect of which they are to make their presentment, contained in the bill of indictment, which directly and unequivocally asserts that a crime has been committed by the party, is or is not true. To return a bill as true upon less evidence than that which, if uncontradicted, would be satisfactory proof of guilt, seems to be at variance with an oath to present the whole truth and nothing but the truth. There appears to be no substantial distinction between a finding by the grand-jury that the party has committed the offence charged, and a verdict of "guilty" pronounced by a petty-jury. The finding of a true bill where the evidence is not sufficient to convict, is a wrong to the party accused. On the other hand, the justice of the country is not unfrequently defeated by forcing on a criminal charge to its final decision at a time when evidence sufficient to show the real character of the transaction has not been obtained; and by the inconsiderate haste of grand-juries in finding bills, the most atrocious crimes have not unfrequently obtained a total exemption from punishment. (8 Howell, 'State Trials,' 821, 836, 838; Burn's 'Justice,' "Indictment V.")

The bill, being indorsed, is brought into court by the grand-jury, and delivered to the clerk of the peace, who reads the indorsement with the name of the prisoner and the nature of the charge. By finding the bill to be true, either generally or in part, the grand-jury are become indictors, and the party charged the indictee; but these terms are nearly obsolete. The indictee is brought to the bar by the jailer, if in custody; or if out on bail, he comes of his own accord in discharge of his bail. He is then arraigned, and the trial proceeds in the same manner as at the assizes. [TRIAL.] If the prisoner be found not guilty, he is immediately set at liberty, unless there be some other matter before the court upon which he ought to be detained. If a verdict of guilty be returned, the sentence is pronounced by the chairman; such sentence, where the amount of punishment attached to the offence is not fixed, being first determined by the opinion of the majority of the justices present.

The sessions cannot be held without the presence of two justices, at least; nor can they be adjourned by one justice, though two or more may previously have been present. Every act done as an act of sessions before two justices have met, or after two have ceased to be present, is void.

The crown may grant a commission of the peace not only for an entire county, but also for a particular district within the county. In order, however, to exclude the interference of the county justices in the particular district, it is necessary either to introduce into the commission of the peace for the particular district a clause excluding the jurisdiction of the county magistrates, which is called a neintromittant clause, or to grant a new commission to the county magistrates excluding the particular district. If the former, which is the usual course, be taken, the county magistrates may still hold their sessions within the particular district, though they can exercise no jurisdiction in respect of matters arising within the district.

Petty and Special Sessions.—A meeting held by justices for the transaction of magisterial business arising within a particular district forming a subdivision of the county or district comprised in the commission of the peace, is called a petty session; and if the meeting be convened for some particular or special object, as the appointment of overseers of the poor, of waywardens, of examiners of weights and measures, &c., it is called a special session. A meeting of magistrates cannot legally act as a special session unless all the magistrates of the particular division are present, or have had reasonable notice to attend.

The statute 12 & 13 Vict. c. 18 makes further provision for the holding petty sessions in counties and boroughs, and declares that every sitting and acting of justices, or of a stipendiary magistrate for a city or borough, having a separate commission of the peace, shall be deemed a petty sessions. The fees of justices' clerks in petty sessions are moreover provided for by the 11 & 12 Vict. c. 43, and 14 & 15 Vict c. 55. [JUVENILE OFFENDERS; JUSTICES OF THE PEACE.]

Borough Sessions.—The Municipal Corporation Act (5 & 6 Wm. IV. c. 76) directs that the recorder of any city or borough to which a separate court of quarter-sessions is granted under the provisions of that Act, shall be the sole judge of such court [RECORDER], leaving the ordinary duties of magistrates out of sessions to be performed by the justices of the peace appointed by the crown for such city or borough. The recorder is required to hold a court of quarter-sessions once in every quarter of a year, or at such other and more frequent times as he may think fit, or as the crown may direct. Borough quarter-sessions are not, however, like county quarter-sessions, appointed to be held in particular weeks. In case of sickness or unavoidable absence, the recorder is authorised, with the consent of the town council, to appoint a barrister of five years' standing to act as deputy recorder at the next session, but no longer. In the absence of the recorder and of any deputy recorder, the court may be opened and adjourned, and the recognisances respited, by the mayor; but the mayor is not authorised to do any other judicial act. Where it appears to the recorder that the sessions are likely to last more than three days, he may appoint an "assistant-barrister" of five years' standing to hold a second court, for the trial of such felonies and misdemeanors as shall be referred to him, provided it has been certified to the recorder, by the mayor and two aldermen, that the council have resolved that such a course is expedient, and the name of the intended assistant-barrister has been approved of by a secretary of state.

Every burgess of a borough (or citizen of a city) having a court of quarter-sessions (unless exempt or disqualified otherwise than in respect of property), is liable to serve on grand and petty juries. Members of the town-council, and the justices of the peace, treasurer, and town-clerk of the borough, are exempt and disqualified from serving on juries within the borough; and they and all burgesses of boroughs having separate quarter-sessions are exempt from liability to serve on petty-juries at the county sessions.

Under the 105th section of the Municipal Corporation Act, the recorder has jurisdiction in respect of all crimes cognisable by courts of quarter-session in counties; but he is expressly restricted from making or levying any rate in the nature of a county rate, or granting any licence to keep an inn, &c., and from exercising any of the powers vested in the town-council. Other matters required by statute to be done at quarter-sessions, and not expressly transferred to the town-council, devolve upon the recorder, as the appointment of inspectors of weights and measures, &c. Persons imprisoned in a borough jail by county magistrates, under 6 & 7 Will. IV. c. 105, may be tried at the borough sessions for offences committed out of the borough.

All criminal jurisdiction which, before the passing of the Municipal Corporation Act, existed in any borough to which no court of quarter-sessions has since been granted, is taken away by the 107th section of that Act.

SESTE'RTIUS, a Roman coin, which originally consisted of 2½ ases, as the name implies, *sestertius* being a contraction of *semis tertius, the third a-half*, which is the Roman way of expressing *two and a-half*. The sestertius belonged both to the brass and silver coinage; and in both it was of the same value, namely, one-fourth of the denarius. This value agreed with its value in ases so long as the denarius consisted of 10 ases. But at an early period the as was reduced in value, and 16 ases made equal to the denarius [AS], and then the sestertius, its value with reference to the denarius remaining the same, became of course equal to 4 ases. On Mr. Hussey's computation the value of the denarius after the reduction was 8½*d.*, and therefore the sestertius was worth 2⅛*d.* After the time of Augustus the denarius was reduced to the eighth of an ounce, and was worth 7½*d.*, and therefore the sestertius was worth 1⅞*d.* The sestertius of the brass coinage was made of the same metal as the as.

The Romans generally reckoned sums of money in sestertii, although the coin used in making payments was commonly the denarius. Large sums they reckoned by *sestertia*, that is, sums of *a thousand sestertii*. It is very important to attend to the phrases used in such computations. The coin itself was called *sestertius*, or *sestertius nummus*, or simply *nummus*. The sum of a thousand sestertii was expressed by *mile sestertii*, or *M. sestertium*, or *M. nummi*, or *M. nummum*, or *nummorum*, or *M. sestertii nummi*, or *M. sestertium nummum*. The singular *sestertium* is never used for a thousand sestertii, but the plural *sestertia* is used for all multiples of a thousand sestertii, up to a thousand; sometimes the word *millia* (thousands) is used instead of *sestertia*; sometimes neither word is expressed; and sometimes *nummum* is added. Thus 600,000 sestertii, or 600 sestertia, might be expressed by any of the following phrases: *sescenta sestertia*, *sescenta millia*, *sescenta* alone, or *sescenta sestertia nummum*. Sums of 1000 *sestertia* and upwards were expressed by the numeral adverbs with the termination *ies*, which implies that the number to which it is affixed is to be multiplied by 100. Thus *decies, undecies, duodecies, vicies tricies, tricies quinquies*, stand respectively for 1000, 1100, 1200, 2000, 3000, 3500 sestertia. These forms are, however, sometimes varied. Thus Cicero ('in Verr.,' ii. 1, 39) uses *quaterdecies* for 1400, and *decies et octingenta millia* for 1800 sestertia. When two such adverbs come together, if the larger is first, they must be added together; but if the smaller is first, they must be multiplied. Thus we have in a passage of Suetonius ('Aug.,' 101), *millies et quingenties* for 150,000 sestertia, and immediately afterwards *quaterdecies millies* for 1,400,000 sestertia. (In the latter case, care must be taken not to reckon the termination *ies* twice over in multiplying; it is not 1400 × 100,000, but 14 × 1000 × 100.)

The symbol HS or IIS is often used both for *sestertii* and for *sestertia*. It stands for *libra libra semis* (two pounds and a-half). When applied to *sestertii* its meaning is clear enough, since the as was originally a pound (*libra*) of brass. When applied to *sestertia* it meant, according to Gronovius ('Pec. Vet.,' i. 4, 11), two pounds and a-half of silver, which he calculates to have been originally equal to 1000 sestertii, and therefore to have represented that value ever after. It is often difficult to determine whether the symbol HS stands for *sestertii* or *sestertia*. When the numeral is written in cipher, and has a line over it, it stands for the adverb in *ies*, and the HS means *sestertia*: thus, HS.$\overline{\text{CCCC}}$ is *quadringenties*, or forty thousand *sestertia*. Sometimes the numeral is found with the singular of *sestertium*, as *sestertii decies*, or *sestertio decies*. Gronovius explains these forms, and also the use of *sestertium* with the adverb in *ies* (which he considers to be, in this case, an accusative singular), by understanding with them the word *pondus*, a pound (of silver), according to which *sestertium* in these forms means two pounds and a-half of silver, or 1000 sestertii. Hence, if these forms are used with a numeral in cipher, they mean the number of *sestertia* represented by the adverb in *ies* of that numeral. Thus *sestertio X* is *decies* or 1000 *sestertia*.

According to the value given above for the *sestertius*, the *sestertium* was worth 8*l*. 17*s*. 1*d*.

The word *sestertius* is often used indefinitely for any very small sum. (Hussey, 'On the Ancient Weights and Money,' c. x., § 1, 3, 6.)

SET-OFF, in law, is the amount of the debt due to a defendant from a plaintiff, which the defendant is entitled to set off in answer either to the whole or part, as the case may be, of the plaintiff's demand. At common law, if the plaintiff was indebted to the defendant in an ascertained sum in respect of the same transaction concerning which the action was brought, the defendant was entitled to deduct at the trial so much from the plaintiff's demand. But if the debt due from the plaintiff accrued in respect of another transaction, the defendant had no such power; and he was either compelled to bring an action against the plaintiff for what was due to him, or, if he wished to avail himself of his cross-demand without bringing another action, to apply after the action had been commenced against him to a court of equity for the purpose of adjusting the claims of himself and the plaintiff. To obviate the expense and inconvenience of such a course, it was enacted by 2 Geo. II. c. 22, s. 13, that "where there are mutual debts between the plaintiff and defendant, one debt may be set against the other;" upon which statute, as explained by 8 Geo. II. c. 24, s. 4, is founded the whole law on the subject. A claim for damages not ascertained cannot be set off, even although they relate to the subject-matter of the action itself. For instance, in an action for goods delivered, the defendant cannot set off the loss which he has suffered by their non-delivery at the proper time, &c. There must also be an entire mutuality between the debt sued for and the set-off. Thus a debt due from the plaintiff together with other parties cannot be set off against a debt due to the plaintiff alone; nor can a debt due to the defendant personally be set off to a demand against him as executor, &c.: and the rule of law is the same for the converse of these cases. It is consistent with this rule that when an action is brought by or against a trustee, a set-off may be made of money due to or from the party for whom he is trustee.

A plea of set-off must describe the debt intended to be set off with the same certainty and particularity as would be necessary in a declaration, which indeed such a plea in several respects much resembles. If for instance a plea of set-off contains several parts stating distinct debts, these are analogous to distinct counts in a declaration, and one may be sustained although the others may not.

SETON. [Issue.]

SETTLEMENT. [Poor Laws.]

SETTLEMENT. A settlement, in the most general sense of the word, is a disposition of property of any kind made for certain purposes by the owner, who, in relation to such disposition, is called the settlor or grantor. A settlement in this case may be made either by deed or by will; but the term is most commonly applied to such settlements only as are made by a deed.

A consideration is not necessary for the validity of a deed at law. Though a deed may in many cases be void as against strangers for want of consideration, it is valid as between the parties. [Deed.] Settlements by deed, therefore, may be either made upon valuable or good consideration, or they may be purely voluntary.

The most important species of settlements—to which, indeed, in strict legal language, the term is exclusively applied—are marriage settlements; and these may be either such as are made previous to and in consideration of marriage, or subsequent to it.

Settlements of property are frequently made by will, with reference to an existing or future marriage. The forms and provisions contained in such instruments are, of course, often very similar to those in deeds made for like purposes. But dispositions of this kind are to be regarded in all respects as wills, and are governed by the same rules as other instruments of the like nature. [Will.]

Settlements in consideration of marriage include not only such as are actually made and executed before marriage, but also such as are executed after marriage in pursuance of articles in writing drawn up and signed before marriage.

1. First, as to the specific performance of articles and agreements to settle property:—

In Equity, no regard is paid to the form of marriage articles, and the construction of them depends entirely upon the intentions and objects of the parties.

When the intended husband and wife are both of full age at the time of the marriage, they are of course competent to enter into any agreement for the settlement of their respective estates, and all such agreements will be enforced in Equity; but if the parties are one or both of them minors at the time, the case is different.

When the husband is adult and the wife a minor, if the subject be real estate of the wife, the husband will be bound by the articles in respect of his marital interest in the lands; that is, for the estate which he takes during the joint lives of himself and his wife, and as tenant by the courtesy if he survive her and there have been issue of the marriage: but the wife will not be bound by them; and, if she die during infancy or after attaining majority, but without having confirmed the settlement in the mode prescribed by the law for disposition of real estate by married women, her heir will take the property unfettered by the articles. Again, if, in the case supposed, the property be personalty of the wife (which, in the absence of a settlement, would become the property of the husband), the articles will be valid as respects both husband and wife, being, in effect, the settlement of the husband. And this is true also as to chattels real and *choses in action* which become reducible into possession during the coverture; but, as to property already settled to the separate use of the wife, and *choses in action* which do not, in event, become reducible into possession during the coverture, the wife will not be bound by the articles.

If a male infant marry an adult female, he is bound by the articles entered into by her for the settlement of her estate, and must execute them when he comes of age, whatever be the nature of the property; but as to his own estate, he will not be bound by them.

When the husband and wife are both minors at the time of the marriage, the articles are absolutely null as respects them, unless confirmed after the attainment of majority. In such a case a confirmation of the articles by the wife must be express, and made in the same manner as any other alienation of property by a married woman; but confirmation on the part of the husband will often be implied from circumstances, such as the acceptance by him of any property under the articles.

It has sometimes been thought that the consent of parents or guardians, and the sanction of the Court of Chancery, might give effect to settlements of their property by infants, which would not have been otherwise binding; but it may now be considered as settled that there is no foundation for such a doctrine.

Marriage is regarded by the law as a valuable consideration, and will support a covenant entered into by a third party to settle property upon the husband and wife and their issue, whether the settlor be one under a natural obligation to make a provision, as in the case of a parent, or merely a stranger; and such a covenant will be enforced not only against the settlor himself, but against his heir, devisee, or personal representative.

Settlements made after marriage, when no valuable consideration (that is to say, no consideration in money or property) is given for them, are generally called, in contradistinction to those made upon marriage, voluntary settlements, and the persons who take under them are called volunteers; though, as such settlements may have good considerations to support them, the application of the term is not always strictly accurate. By a good consideration, as distinguished from a valuable one, is here meant that love and affection which is naturally supposed to subsist between near relations, such as parents and children, brothers and sisters, uncles and nephews or nieces.

Specific performance of voluntary covenants to settle property will be enforced in Equity only in favour of those persons for whom the covenantor is under a natural and moral obligation to provide; that is to say, in favour of his wife or children, but not in favour of any other class of volunteers. If, however, any valuable consideration has really been given, either by the person who, by himself or his representative, claims execution of the articles, or by a third person, in favour of the object of the limitation, specific performance will be decreed, and no objection can be made on account of want of relationship between the parties; and, for this purpose, it is sufficient if the fact of a consideration being given can be inferred from the circumstances. Though a person whose claim is not supported by a good or valuable consideration cannot himself compel the execution of articles in his favour, he may yet have the benefit of a suit instituted by another; for in decreeing specific performance, the court executes the entire articles, though they may embrace limitations to persons in whose favour it would not have originally interfered.

2. Next, as to the validity of marriage settlements against creditors and purchasers.

Marriage being a valuable consideration, the circumstance of the settlor being indebted, or even insolvent, at the time of the execution of the settlement, can have no effect on its validity, even though the persons who have the benefit of the settlement should have full notice of such insolvency. A conveyance or assignment of property in consideration of marriage stands on the same ground with a sale for money, which is not affected by the insolvency of the vendor. If, however, the settlor be a trader, and a fiat in bankruptcy be issued against him prior to the execution of the settlement upon which he is afterwards duly found a bankrupt, such settlement, like all other conveyances of the bankrupt under the same circumstances, will be void; and it would seem that a settlement must in all cases be void as respects the wife, if she had notice of a prior act of bankruptcy, and a petition be filed within twelve calendar months after such act of bankruptcy. (2 & 3 Vict. c. 11, s. 13.)

The marriage consideration does not extend or give the character of purchasers to all persons in whose favour limitations may have been introduced into the settlement. In relation to any other persons than the husband and wife and the issue, the settlement is, it seems, to be considered as voluntary, and subject therefore to the rules applicable to voluntary gifts and covenants.

Settlements made after marriage, it is obvious, can derive no support from the consideration of marriage, and their validity or invalidity must therefore depend upon other circumstances.

A postnuptial settlement by the husband, of any species of property made in consequence of a valuable consideration moving either from the wife herself, who gives up an interest that she possesses in property over which she has a disposing power, or from her relations or friends, is good against all persons whatsoever, if the consideration be not so inadequate as to raise the presumption of fraud. And even in case of inadequate consideration, the settlement, it seems, will be good to the amount of the consideration. It is sufficient if the consideration, though not paid, is properly secured. Contemporaneous settlements will in general be presumed to have been made in consideration of each other; and it seems that parole evidence of consideration is admissible, though none appear upon the instrument itself.

The statute 13 Eliz. c. 5, enacts that "all conveyances, &c., of lands and tenements, goods and chattels, made of malice, fraud, covin, collusion, or guile, for the intent or purpose of delaying or defrauding creditors and others of their just and lawful actions, suits, debts, &c. shall be deemed and taken (only as against those persons, their heirs, successors, executors, &c.) to be clearly and utterly void, frustrate, and of none effect; any pretence, colour, feigned consideration, expressing of use, or any other matter or thing to the contrary notwithstanding." But the act is expressed not to extend to any interest or estate made, conveyed, or assured, upon *good consideration and bonâ fide*, to any person or persons "not having at the time of any such conveyance or assurance to them made any manner of notice or knowledge of such covin, fraud, or collusion as is aforesaid." Upon this statute it has been determined, (1) That if the settlor be not indebted at the time, the settlement, even though entirely voluntary, is good against subsequent creditors; (2) That the mere existence of debts at the date of the settlement will not invalidate it if the settlor be solvent—that is, if he be possessed of property sufficient for the payment of his debts independent of the property so aliened; (3) That a settlement which might have been invalidated in the hands of the donee will be good against the creditors of the donor in the hands of a purchaser from the donee for valuable consideration without notice.

Voluntary obligations not affecting particular property, such as bonds, though the grantor should have been solvent at the time of making them, will not, it seems, entitle the grantee to come in *pari passu* with creditors for value, who will always be preferred; but the cancellation or release of a voluntary obligation, if untainted by fraud, may form a valuable consideration for the conveyance of property or for a substituted engagement.

By the 27 Eliz. c. 4, all conveyances, &c., of lands, tenements, or hereditaments are declared void when made with intent to defraud subsequent purchasers for money or other good consideration; "any pretence, colour, feigned consideration, or expressing of any use or uses, to the contrary notwithstanding." There is a saving of all conveyances made upon *good consideration and bonâ fide*. It also makes void, as against the same persons, all conveyances "with any clause, provision, article, or condition of revocation, determination, or alteration at (the grantor's) will or pleasure," whether such clause extend to the whole interest conveyed, or only partially affect it; but then follows a proviso "that no lawful mortgage made *bonâ fide*, and without fraud or covin, upon good consideration, shall be impeached or impaired by force of this act." This statute has been construed to extend to all voluntary conveyances, though not in fact made with intent to defraud, and though the purchaser had notice of the prior conveyance. The consequence of this is, though probably not intended by the framers of the Act, that it is impossible to make an irrevocable free gift of lands or tenements.

The statute 27 Eliz. c. 4, does not apply to personal estate. It has been determined on this act, by analogy to the determination on the last-mentioned act as to creditors, that a purchaser from a voluntary grantee will be preferred to a subsequent purchaser from the grantor. The *good* consideration mentioned in this and the preceding statute must be a valuable consideration (that is to say), either a property or marriage consideration. The consideration of blood has no application to either of these statutes, and therefore a conveyance made in consideration of "natural love and affection," as in the case of a postnuptial settlement upon a wife and children, is considered, for the purposes of these statutes, as voluntary. It has been decided, however, that a husband, having made a voluntary settlement on his wife and children, has no equity to compel specific performance of his contract with a subsequent purchaser; but he can sell the property which he has so settled, and the purchaser will have a good title, and can enforce performance of the contract for sale, if the husband should refuse to convey the property.

By stat. 21 Jac. I., c. 19, all voluntary settlements of traders were invalidated by their bankruptcy, though they might have been solvent at the time of making them; but the stat. 6 Geo. IV., c. 16, s. 73, and 12 & 13 Vict., c. 106, s. 126, placed the settlements of traders on the same footing with voluntary alienations in general.

Property cannot be settled so that the interest taken by any person under the settlement shall be unaffected by his bankruptcy; but it may be given to a man until he shall become bankrupt, provided there is a gift over of the property on that event. In the same manner the property coming from the wife may be settled on the husband so as to be devested on his bankruptcy. But when the property is the husband's own, it has been determined that, though the claims of the husband's creditors might have been defeated by a trust of the whole for the separate use of the wife, a limitation of the property to the husband until his bankruptcy, with a gift over in that event to the wife or any other person, is void. Upon the same principle, a bond or other obligation given by the husband upon his marriage, conditional for the payment of a sum of money to trustees for his wife and children in the event of his bankruptcy, is void as against his creditors who claim under the fiat or adjudication, if he has received no portion with his wife; but if he has received a portion with her, the obligation, being considered so far as a settlement of the wife's property, will be good against the creditors to the extent of it.

3. As to secret settlements and agreements in fraud of the marriage contract.

Secret settlements of her property made by the wife pending the treaty for marriage, without the privity of the husband, are void as against him, if made in derogation of his marital rights; and this, it seems, is equally true, whether the husband knew of the existence of the property before the marriage or not. The rule applies to every species of gratuitous incumbrance created by the wife upon her property under such circumstances.

The courts of equity, upon the general principles on which they act in cases of fraud, will set aside all secret covenants or agreements entered into contrary to the good faith of the marriage treaty, and not with the privity of all the parties to the settlement. Relief in such cases will not be refused even to a person who was a party to the fraudulent transaction of which he complains.

Upon the same principle, if a creditor or holder of any security or charge on the estate of one who is engaged in a treaty of marriage, misrepresent the amount of his debt or incumbrance to any of the parties to the contract, whether for the purpose of promoting the marriage, or for any other purpose, he will be bound by such misrepresentation. Money which has been lent to a woman for the purpose of being represented as her own, cannot, after the marriage, be claimed as a debt from the husband.

4. Settlements of real property usually consist of limitations of an estate or estates for life to one or more persons, that is (where the settlement is made on marriage), to one or both parents and the survivor of them, with remainders over to their children. This is what is called a limitation in strict settlement. By this method the estate is rendered inalienable till the eldest son of the marriage attains the age of twenty-one, when he can join with his father in barring his own estate tail and all the remainders over, whereby a new estate in fee simple is acquired, and the property may be settled again. [PRIMOGENITURE; REMAINDER.] This was formerly effected by means of a common recovery [RECOVERY], but it is now effected by a deed executed under the provisions of 3 & 4 Wm. IV., c. 74. By this act fines and recoveries are abolished, and the objects of these old modes of assurance are now obtained by a deed which must be enrolled in Chancery within six months after its execution. As, before this act, a tenant in tail expectant on a particular estate of freehold could only have barred his own issue by a fine [FINE], unless he could obtain the concurrence of the owner of the particular estate in suffering a recovery, so, under the new act, his power is equally limited, unless he can obtain the concurrence of the owner of the first existing estate under the settlement (whether it be for life or lives, or any greater estate, not being an estate for years) prior to the estate tail, who is called the protector of the settlement. The act contains several provisions for the purpose of ascertaining who shall be protector in the cases of joint ownership, coverture, and the existence of estates for years or in dower; and it provides for the cases where the protector is a lunatic, or convicted of treason or felony. The act also gives the settlor power to appoint by the deed a protector of the settlement, in lieu of the person who would otherwise have been the protector. The consent of the protector must be given either by the deed of assurance or by a separate deed, which must be enrolled in the same manner as the assurance itself. The same act repeals (except as to settlements made before the 28th of August, 1833) the statute of 11 Hen. VII.,

c. 20, whereby women who were seised of estates tail of the gift of their husbands (*ex provisione viri*) were prohibited from alienating them.

The estates limited in settlements of real property may be either legal or equitable. [Uses.]

When charges are intended to be created upon real estate, as for jointures or portions for children, it is usual to limit terms of years out of the estate to trustees for securing payment of the charges by perception of the rents and profits, or by sale or mortgage of the estate for the periods so limited. These terms are inserted at proper places in the settlement, according to their objects, among the other limitations; and such limitations as are subsequent to these terms of years in the order of arrangement, are also made subject to them in point of legal and equitable interest. It is usual to provide that the terms shall cease when their objects are accomplished or become unnecessary or incapable of taking effect.

Estates for lives and terms for years are incapable of being entailed; but they, as well as personal property of any kind, may be settled in trust as effectually, and so as to be inalienable for as long a time as estates of inheritance. The property in such settlements is usually assigned to trustees in trust for the husband, or for the husband and wife for his or their life or lives and the life of the survivor; and then in trust for the first and other sons severally, and the heirs of their bodies. This limitation vests the absolute interest in the eldest son, who will be entitled to dispose of the property upon his attaining the age of twenty-one; but in order to provide for the event of the eldest son dying under age and without issue, in which case his interest would otherwise vest in his father, if alive, as his heir or next of kin, it is usual to introduce a proviso that the property shall not vest absolutely in any son dying under the age of twenty-one years and without issue; and it has been determined, that, in construing settlements of both real and personal property, when the real estates are limited in strict settlement, and the personal property, according to a form frequently adopted, upon and for the same trusts, estates, and purposes as the freeholds, as far as the law will permit, a proviso of the kind above-mentioned is to be understood.

There is no restriction as to the number of life estates which may be limited in settlements to take effect in succession, provided the persons be all in existence at the date of the settlement; for, in point of fact, this amounts to no more than an estate for the life of the survivor.

Thus it appears that real or personal property may be settled so as to be inalienable for a life or any number of lives in being, and twenty-one years after. To this must be added a period of nine months, which is allowed for the birth of a posthumous child in cases where gestation exists. As the period of twenty-one years was no doubt adopted originally with reference to the term of minority, which must elapse before an estate tail could be barred, it was formerly thought that this period could not at all events be added to an executory trust; but it is now settled otherwise. All restraints on alienation beyond the above-mentioned limits are void, as tending to what is called in law a perpetuity; and all the subsequent limitations, if contingent, are also void. The same rules are applicable to executory devises, and springing and shifting uses [Wills; Uses]; but not to remainders limited to take effect after estates tail, which are not subject to any restriction; because, as such limitations may be defeated at any time by barring the estates tail, they can have no tendency to a perpetuity.

The forms of settlements may be varied according to the objects and intentions of the parties, and the construction of the articles upon which they are founded. The principle upon which a Court of Equity acts in executing marriage articles, is to look rather to the intentions of the parties as deducible from the circumstances, than to the literal meaning of the words employed by them. Thus, when the words used in articles concerning the settlement of real estate are such as would give the father an estate tail, and thereby enable him to defeat the settlement, the court will in general direct limitations in strict settlement to be executed, under which the father will take a life estate only. Upon the same principle, even though a deed of settlement has actually been executed after marriage, if it appear to be in any respects inconsistent with the letter or spirit of the ante-nuptial articles, the court will rectify it.

Questions frequently arise as to what powers, covenants, and provisos are to be introduced into marriage settlements made in pursuance of executory trusts, whether created by articles, wills, or other instruments. The determination of these depends entirely upon the rules of construction as applied to each particular case.

Of the powers usually introduced into settlements of real estate, the most important are—powers of jointuring and raising portions; powers of leasing and management; and powers of sale and exchange.

Where the wife, upon whose marriage the settlement is made, does not take a life interest in the estate in the event of surviving her husband, provision is usually made for her by way of jointure in bar of dower. [Jointure; Dower.] In addition to this, powers are frequently introduced to enable the husband, in case of his surviving his wife, and marrying again, and sometimes also the other tenants for life under the settlement, to make provision for their widows, by way of jointure, which the nature of their estate would not have otherwise entitled them to do. Powers of jointuring, and powers for charging the estate with portions for the benefit of the younger children of the then existing or a future marriage, will not, it seems, be inserted in settlements executed under the direction of a Court of Equity, without clear authority for them in the articles; for without such authority the court can have no data by which to regulate the quantum of interest to be taken by the donees.

Powers of leasing for the usual term of twenty-one years are essential to the management of an estate, and will be considered as authorised by the use of the most general expressions in the articles; or perhaps introduced as a matter of course; but a power to grant building leases will not, it seems, be implied without express authority.

Powers of sale and exchange are also considered as usual powers in a settlement, and will be authorised by the use of very slight expressions in the articles.

In settlements of personalty, where the property is assigned to trustees, they are empowered to invest and lay out the funds, and also to vary the securities from time to time. After the declaration of trusts for the husband and wife and children, such settlements usually contain powers of providing for the maintenance, advancement, and education of the children who are or may become entitled to shares in the funds under the preceding trusts.*

Settlements both of real and personal estate usually conclude with what are called trustee clauses, that is to say, clauses which enable the trustees to give effectual receipts; to provide for the appointment, when needful, of new trustees; for the indemnity of the trustees against involuntary losses; and for the payment of their expenses.

Marriage settlements sometimes contain covenants to settle particular lands; covenants to settle, or to purchase and settle lands of a certain value, or future real estate; covenants to settle present or future personalty; and covenants by parents, on the marriage of one of their children, to leave to that child an equal or some proportionate share with the rest.

The covenant to settle particular lands of course binds heirs, devisees, and all into whose possession the lands come, except a purchaser, for valuable consideration without notice; and, in case of the lands being so alienated, satisfaction may be claimed out of the general assets of the covenantor.

Questions frequently arise upon covenants to settle, or to purchase and settle lands of a particular value, as to what amounts to performance. On this point the following positions appear to be established:—1. Where the covenantor has no lands at the time, any purchase he may afterwards make will be presumed to have been made in pursuance of the covenant; 2. It seems, though there are conflicting authorities upon the point, that if the covenant be *to settle*, and the covenantor, having at the time lands adequate to the performance of the covenant, die without making any purchase, the lands which he had at the time will be bound to the extent of the covenant; 3. Where the covenant is to *purchase and settle*, it seems that no lands of which the covenantor is seised at the time will be affected, but all after-purchased lands will be affected to the extent of the covenant.

Covenants to settle future real estate of which the husband shall become seised during the marriage, or during his life, do not affect lands of which the covenantor is then seised, but extend to all after-acquired lands, even to such as come to the husband under the provisions of the deed of settlement.

Covenants to settle present or future personalty are considered as applying to capital only, not to income. If real estate should have been purchased with the personalty subject to such a covenant, the land is not bound *in specie* by the covenant, but is charged with the money invested in the purchase.

Covenants to leave one child an equal or proportionate share with the rest, attach only upon that portion of the settlor's property which may remain at the time of his death. The parent may therefore make an absolute gift of any part of his property in his lifetime to another child without committing any breach of his covenant; but a gift reserving any interest to himself is a breach of it. The benefit of such a covenant is confined to children living at the death of the parent.

5. Marriage is not an absolute gift to the husband of the wife's personal estate, but only entitles him to so much of it as he may have reduced into possession, assigned or released during his lifetime. Accordingly, questions frequently arise upon settlements as to the title of the husband, under them, to the whole of his wife's fortune. Upon this point the following propositions appear to be established:—1. The antenuptial settlement of property made by the husband upon the wife, in consideration of her fortune, entitles him only to her *then*, and not to the *future* personal property; 2. That if a part only of her fortune appears to have been stipulated for, the residue of what she then has, or what may afterwards accrue to her, will not belong to the husband; 3. That when it appears from the settlement, either expressly or by implication, that the agreement was for the whole of the

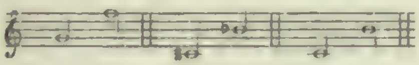
---

* Similar clauses are contained in settlements of real estate, where there are trusts for raising portions.

wife's present and future personal estate, the husband, or his personal representative (in case of his predeceasing his wife), will be entitled to claim the whole under the contract.

When the husband has not entitled himself by contract to the *choses in action* of the wife, there is no bar to his getting possession of such of them as are recoverable at law; but if he require the assistance of a Court of Equity for the recovery of them, and the wife does not consent to his obtaining the whole, that court will not lend its aid, except upon the terms of the husband's making a provision for the wife and her children, by way of settlement, out of the fund. Most frequently one half of the fund is directed to be settled, but the proportion given in each case depends upon the circumstances, though it never amounts to the whole. The rules of the Court of Equity in directing settlements out of the wife's equitable *choses in action* are the same, whether the application to it is made by the husband himself or by his creditors. Settlements out of the wife's equitable *choses in action*, when made by the husband, are no less valid against his creditors than when made under the direction of the court; and even a settlement by him of the entire fund, which the court would not have directed, has in some cases been held valid against his creditors; though the decisions in those cases seem hardly consistent with the law as laid down under the 13 Eliz., c. 5. It should be added, that now by the stat. 20 & 21 Vict., c. 57, a married woman is empowered to release, with the concurrence of her husband, her equity to a settlement in property to which she may be entitled under any deed dated subsequently to December 31, 1857; also to dispose of reversionary interests under such settlements. But these enactments do not interfere with the principles above stated. (SEPARATE USE; Bright on *Husband and Wife.*)

SEVENTH, in music, a dissonant interval, of which there are three kinds,—the minor or ordinary seventh, from G to F; the diminished seventh, from C sharp to B flat; and the major or sharp seventh, from C to B. Ex.:



For the *chord* of the seventh, its inversions and treatment, see CHORD.

SEWERS. In its original acceptation, the word Sewers meant simply the banks, or sea-weirs, erected for the purpose of protecting the low lands by the sides of tidal rivers, from the effects of inundations or high tides; but, by extension, the word has been applied firstly to all artificial channels which discharge the surface drainage of lands on a comparatively speaking high level into a natural water course, by outlets on its shores (whence the old synonyme for sewer, *shore*); and of late years the word has been so exclusively applied to the subterranean artificial water-courses of towns destined to relieve them of both the surface drainage, and the liquid refuse of the houses, as to have caused the original meaning to be entirely lost sight of. It is however so convenient to adopt a special name for town drains, and the modern sense of the word *sewer* is so universally received, that in the succeeding remarks, it will be exclusively so employed; or, in other words, whenever *sewer* is used, it will be in the sense "of an artificial channel for the removal of surface, subsoil, or house waters."

The earliest recorded instances of the use of sewers is in the palace of Nimroud, and in the more celebrated Cloacæ of ancient Rome; but none of the drains of this description executed by the ancients were used for the purposes to which they are applied in the more highly civilised countries of modern times. The cloaca maxima itself was formed for the purpose of draining the Campus Martius, and the low swampy lands between the Seven Hills, in precisely the same manner that the Égout de ceinture of Paris drains the valley of the Marais, Menilmontant, and Montmartre of that city; and though no doubt the house waters of the capital of the ancient world found their way eventually into this huge drain, it is notorious that the Romans never were acquainted with the modes of house sewerage we have lately applied. One of the first legislative enactments of modern times on the subject of sewers was an act, 9 Henry III. (about 1225), which was followed by others, 6 Henry VI.; 8 Henry VI.; 4 Henry VII.; 6 Henry VIII.; and the whole of the legislation then prevailing was carefully reviewed and condensed, by Sir Thomas More, in the celebrated 'Bill of Sewers,' which became law in 25 Henry VIII. (or in 1531). In France attention had also been directed to the subject of the drainage of the capital towards the close of the mediæval period, for in 1412 the grand Égout de ceinture (then called the ruisseau de Menilmontant) was built; and in 1550, Philibert de l'Orme was instructed to examine and improve the drainage of Paris. The governments of both England and France continued from these periods actively to interfere with the regulation of these important works; but, in accordance with the respective idiosyncracies of the two nations, the courses adopted were essentially different. In the one case, the power was handed over to local commissions; in the other, it was retained exclusively in the hands of the central government; the consequence being, as might have been expected, that in the former case there was displayed much irregular energy and enterprise, in the latter there was displayed a singular amount of scientific indifference. Without dwelling on this political part of the questions connected with the execution of public works, it is to be observed that ultimately, about the year 1834, there were no less than eight separate commissions entrusted with the superintendence of the sewerage and drainage of London; and so great were the evils then found to result from the variety of practice tolerated by the different boards, and from their discordant jurisdictions, that at last, after many efforts, the local boards were suppressed, and in 1848 the "Metropolitan Commissioners of Sewers" were appointed, with extensive powers over the whole of the Metropolis. A few years later the management of the sewerage of the Metropolis was transferred to the Metropolitan Board of Works instituted by the Act of 18 & 19 Vict. c. 120 (passed 14th August, 1855). The sewerage of the provincial towns of England is now either left under the control of the local paving and draining commissions, or of the municipal corporations acting under special acts of parliament; or it is carried on under a species of government superintendence, under the powers of the Public Health Act, 11 & 12 Vict. c. 63 (passed 31st August, 1848), which has been limited by the passing of some subsequent acts, such as the Act of 1854, and the local government act of 1858. In France the administration of the laws regulating the Égouts remains under the control of the Department of Public Works, and the Municipalities have practically no power over the matter.

Until a very recent period, the subterranean channels of London were exclusively used as drains for the removal of surface, subsoil, and ordinary house waters; and the discharge "of any filth or soil into any common, or public drain, or sewer" was even, by the Act 57 Geo. III. c. 29, made punishable by a fine. Subsequently to that period, however, the universal application of the water closet system has forced the various authorities connected with the sewers to tolerate in the first place, and finally to regulate, the discharge of the excreta of the inhabitants of towns into the sewers. To such an extent does this now take place, that the modern use of those subterranean channels has become of infinitely more importance than the original one, and the word "sewerage," or sewage, has been invented for the purpose of expressing the waters employed for the removal of house refuse of the description alluded to. Unfortunately the legislature has hitherto neglected to direct its attention to the evil produced by the new system, by thus discharging, eventually, the whole of the town refuse into the natural water courses of the country; and though no doubt many of the details of the sewerage of our towns have of late years been much improved, much still remains to be done, not only for the purpose of securing the purity of the rivers and streams, but also for the useful application of the fertilising matters now so sadly wasted.

One advantage appears to have resulted from the discussions which have taken place with respect to the legislative, administrative, and executive measures required to meet the case of the metropolitan sewerage, namely, that at last many of the exclusive theories propounded by the admirers of hydraulic engineering, as it is *not* practised by *eminent* hydraulic engineers, have been set aside; whilst all that was good in the technical modes of operation introduced by this new school has been retained. At the present day the principles most generally admitted as being applicable in designing a complete system of town sewerage may be stated to have been elicited from the discussions thus referred to, and to be as follows, in all normal cases at least. It must, however, be understood that they are based upon the supposition that the town in question is in a thriving condition, and likely to double its population in fifty years; that its relief is such as to afford tolerably favourable rates of inclination in the main sewers; and that there is a good water supply to every house. The rain-flow to be provided for from the paved and non-absorbent parts of the town, may be taken at about ¼ inch in 24 hours if proper storm overflows can be obtained; that from open gardens, cultivated lands, &c., may vary according to the nature of the soil, from ¼ inch to ½ an inch per day Under-ground springs must be allowed for, if they should exist in any serious quantities, as is frequently the case in towns situated upon the outcrop of a geological stratum, or upon a bed of permeable materials surrounded by high lands able to drain into them. In some cases, the latter condition may even require that a system of intercepting drains should be formed, so as to isolate the area of the town from the hydrographical basin surrounding it, and to confine the sewerage operations to that especial purpose.

These conditions premised, before settling the dimensions of the main sewers, it is necessary to divide the town into sections corresponding with the great physical divisions of the district, and to ascertain for each of the latter: 1, the area to be relieved; 2, its actual and prospective population; 3, the amount of the house sewerage it would be likely to furnish (this is usually at the rate of 5 or 7 cubic feet per individual, and it is found that at least one-fourth of that quantity is discharged between the hours of eleven and one, so that it is advisable to calculate the house sewerage at nearly 1 cubic foot per head per hour); 4, the rain-flow; 5, the length of the sewer, and the inclination it would be possible to give to its invert, because the two last named conditions will affect the dimensions of the cross section. As to the house sewers, it is useless to attempt to proportion their area and fall to the quantity of waters they may discharge, because it has been found practically that the public in general is so careless in its manner of treating those sewers, that anything less than a 6-inch pipe drain will infallibly be choked within a very short time. So long as the pipe drains thus referred to run under the houses themselves, they should be jointed in cement, and under all circumstances they should be without junctions at right angles. The highest point of the sewer should be laid, if possible, at 2 feet at least below the lowest part of the basement story it is intended to drain; and it would be desirable to make the longitudinal fall about 1 in 65; the house sewers should be made perfectly impermeable, and if any land springs should happen to occur in the surface occupied by the house they should be carried off by a special system of drains. In order to guard against the flooding of basements, by any accidental accumulation of waters in the main sewers, it is desirable that the connection between them and the house sewers should be effected at a small height above the upper line of the invert of the main sewers; but care must be taken to prevent the formation of any current, or of any obstruction, able to produce a deposit near the point of junction. Especial precautions must be taken to trap all communications with the sewers which might otherwise admit the escape of gases into the house; all rain-water pipes should discharge their waters into the upper ends of the sewers, if possible; and under some circumstances the rain-water pipes may be made to serve as ventilators to the sewers, when their joints are remarkably well made, and the heads are fixed above every opening of the house. One of the favourite theories of the late General Board of Health was to the effect, that what was then called "combined back drainage" (or the connection of a number of small house sewers at the back of the blocks of houses, with other small sewers of an area barely sufficient to discharge the united amounts of sewerage), was the cheapest and best method of removing those waters; but so many serious inconveniences have been found practically to attach to this system, that at the present day it is generally abandoned, and the house sewers are almost always carried directly from each house into the main sewers in front of them.

In the execution of the street sewers (the sub-mains, in fact, of the sewerage of a town), care must be taken that their dimensions should be sufficient to carry off any occasional storms; that means should be provided for the easy examination and repair of the works; and that no obstacle should be presented of a nature to provoke a deposit of the matters brought from the houses, or from the streets themselves. The junctions of the house sewers should be made with curves of considerable radius; the surface waters from roads and streets must be received in trapped cesspools, so constructed as to intercept all solid matters, and to collect the fine mud washed from those surfaces in an available form, because it is often of commercial value as a manure; the ventilation of the sewers must be effected in such wise as not to inconvenience the dwellers in the neighbouring houses, and for this purpose it is preferable to insert ventilating holes in the middle of the roadway, whilst the side gullies should be carefully trapped; and side entrances with flushing gates, or other machinery, must be provided according to the local peculiarities of the sewer. The principles which regulate the size and the materials of street sewers are, firstly, that the smallest possible frictional area should be presented to the flowing current, and that the water should flow without being under pressure; secondly that the actual channel for the sewerage should be impermeable, but there are some cases in which it is actually desirable that the sewer should give free passage to the land waters at levels above the line of their own maximum flow. Now of all forms of cross section, a semicircle is the one which presents the smallest frictional area; and it may be laid down as a law that, in most cases, the impermeable cylindrical stone-ware pipes are the best materials which can be employed for street sewers, provided their dimensions are not required to exceed 2 feet in diameter; beyond that diameter, however, it is difficult to obtain pipes of a sound character, and they become more expensive than brick culverts of the same area. There is another consideration which also requires to be taken into account, in cases wherein the diameter of the water-course exceeds 2 feet, namely, that it frequently becomes necessary to cleanse them by hand labour. A man can crawl through an oval channel 2 feet wide by 2 feet 6 inches high, so that those dimensions may be taken as the minima ones for street sewers in districts where it would be difficult or objectionable to open the roadways; and sewers of such forms are far more conveniently made in brickwork, than in stone-ware pipes. Brickwork sewers, moreover, present the advantage of allowing lateral junctions to be made more easily than would be the case with stone-ware pipes. The sizes of street sewers usually adopted, when the requisite dimensions exceed an area equal to that of a semicircle of 2 feet in diameter, are (the transverse section being now made of an egg shape) either 3 feet 3 inches deep, by 2 feet wide at the minor axis; 4 feet, by 2 feet 6 inches; 4 feet 9 inches, by 3 feet; 5 feet 6 inches, by 3 feet 3 inches. The dimensions of such sewers as the Fleet sewer of course cannot be brought under any normal law, for it drains an area of not less than 4400 acres, half of which is covered by houses, and has been known to run with a stream of not less than 106 feet superficial area. The best velocity of the flow in street sewers is about 1¾ to 2 miles per hour, and the rate of inclination of the bed should as far as possible be made equal to 1 in 240; below that inclination it becomes necessary to flush the sewers from time to time, in order to keep them clear. The junctions of street sewers with one another should be made with their centre lines of invert on the same level; the junctions of these sewers with the main sewers should, however, take place so that the centre line of the latter should be a few inches below those of the branch sewers.

As frequent allusion has been made to the land waters it is often requisite to remove by the means of sewers, it may be as well to observe that unless drains should be laid down for the express purpose of relieving the subsoil of those waters, or unless there should exist some natural outlet for them, the main and sub-main sewers should be made either with inlet holes or of partially permeable materials above the level of the ordinary storm flow of the sewerage. Sufficient attention is rarely paid to this condition of the soil of sandy or of gravelly districts, and it frequently happens that, in towns wherein a good system of house sewerage exists, the basements are flooded by the land waters, because the latter cannot find their way into the impermeable main sewers. When the feeding grounds, so to speak, of the springs are extensive, the best course certainly is to execute an intercepting drain, so as to separate the inhabited area of the formation from the open soil of the country. An instance of the evil thus alluded to is to be found at Southampton, and another in the quartier Montmartre in Paris; and in both of them the inundations of the basements, after long-continued wet weather, are often productive of serious evils. Perhaps it may be desirable to cite, as an additional reason for preferring the construction of a special system of intercepting or land drainage for the removal of the springs, that when they are removed by the agency of the sewers there is a possibility that the foul waters flowing in the latter may permeate the land around them at certain seasons. As a general principle it would unquestionably be preferable to confine the drains and sewers to their respective functions; but in this, as in all cases connected with practical engineering, local considerations may often render it prudent to modify absolute theoretical laws. It is worthy, however, of especial remark that the formations which are thus exposed to become charged with underground waters, are characterised by the frequency and the violence of the typhoidal fevers which prevail amongst the town populations located upon them. As a sanitary measure, the drainage of such lands is nearly as important as the sewerage of the houses and streets can be.

The main drains of a system of town sewerage are of course to be calculated as to their dimensions upon the same principles as the sub-mains; that is to say, they must be proportionate to the area, the rain flow, and the amount of sewerage, to be dealt with. The waters coming into the mains are usually animated by a velocity rather in excess of the one which would be requisite to maintain the rate of flow necessary to preserve a clear channel for the larger volume of water in the united stream; and from the ordinary laws of hydrodynamics it follows that the inclinations of the main sewers may without inconvenience be made less than those of the sub-main sewers. It is, however, desirable to keep the inclinations of the former at least at the rate of 1 in 500, though occasionally when great facilities for examination and repair may exist, that rate may be reduced, without serious inconvenience, to 1 in 1000. Great precautions are required in the construction of main sewers to secure an efficient ventilation; and, wherever it is possible so to do, storm overflows should be provided. This latter precaution of course can only be adopted when the discharge of the contents of the main sewer takes place by gravitation; if the discharge should take place by artificial means, it will be found necessary to construct the main sewers of dimensions able to contain any occasional accumulation of storm waters.

Hitherto the final discharge of sewerage waters has been effected by merely pouring them into any natural water-course, to the great injury of the latter, and to the great disgrace of the authorities who pretend to watch over the sanitary interests of the country. It is true that some very earnest attempts have been made to apply the sewerage to the purposes of agriculture, both in a solid and in a liquid form; and it is equally true that hitherto those attempts have not been successful in a commercial point of view. Nevertheless, the importance of the subject, as proved by the gradual contamination of the Thames, for instance, is so great that no mere money considerations ought to be allowed to stand in the way of the compulsory application of some efficient measure for the deodorisation and purification of town sewerage before its discharge into any superficial water-course. The experiment tried at Leicester, of precipitating the solid matters from the sewerage, has proved at least that the operation can be effected at a moderate rate per head of the inhabitants of a town; the results of the Rugby and Watford experiments, of pouring the sewerage in a liquid form over agricultural lands, although far from successful up to the present, have not been of a nature to discourage further attempts to dispose of that fluid by irrigation, especially in agricultural districts. In the case of Rugby the sewerage is distributed, over a mixed area of arable and of pasture lands, by a system of cast-iron pipes and moveable hose, which has necessarily increased the first cost of the distributing apparatus and of the subsequent working; if, instead of these costly follies, the sewerage had simply been pumped up to a high level, and a surface irrigation by gravitation had been thence effected, the results would in all probability have been very different from those which were actually obtained.

Some idea of the importance of the sewerage works lately executed in England may be formed from the facts that there is now hardly a town wherein they do not exist in a more or less perfect form; and that the average cost has latterly been at the rate of at least 1*l.*

per head of the population of the towns. The average sewers-rates of well-drained towns seem also to be about 2½ per cent on the rental of the houses.

It may be added that in the London sewerage there appears to be present about 1 ton of solid matters to every 266 tons of water; but in very unfavourable cases the proportions of solid to liquid may increase to 1 in 96, or even to 1 in 36; the proportion of 1 in 66 is considered to be the largest which is consistent with the safe working of pipe sewers, in which the fluid can move with a velocity of 3 feet per second.

(Consult 'Reports of Health of Towns Commission,' and the various Blue Books on the London Sewers; 'Transactions of Civil Engineers;' 'Annales des Ponts et Chaussées,' &c.)

SEXAGESIMA, the second Sunday before Lent, or the next to Shrove Tuesday; so named, as being, not exactly, but about the sixtieth day before Easter. Brady, in his 'Clavis Calendaria,' vol. i., p. 175, says, "The name of the first Sunday in Lent having been distinguished by the appellation of Quadragesima, and the three weeks preceding having been appropriated to the gradual introduction of the Lent fast, it was consistent with propriety to call the three Sundays of these weeks by names significant of their situation; and reckoning by Decades, the Sunday preceding Quadragesima received its present title of *Quinquagesima*, the second *Sexagesima*, and the third *Septuagesima*.

SEXAGESIMAL, a name given to the system of reckoning in which each unit is the sixtieth part of the preceding, to which, in our day, we are only accustomed by the method of measuring angles and time. The Greeks, and Ptolemy in particular, brought this method into use in astronomical matters, and their successors seem to have attempted to make it a general mode of reckoning. There exist treatises of arithmetic fashioned on this system; one, for instance by BARLAAM. [BIOG. DIV.]

In the sexagesimal arithmetic, $17\ 26'\ 48''\ 53'''\ 9^{\mathrm{iv}}$ stands for 17 units + 26-sixtieths of a unit, or 26 minutes or *scrupula prima* [SCRUPLE] + 48-sixtieths of a minute, or 48 seconds or *scrupula secunda* + 53-sixtieths of a second, or 53 thirds or *scrupula tertia* + 9-sixtieths of a third, or 9 fourths or *scrupula quarta*.

Addition and subtraction are easy enough in this system; multiplication, division, and the extraction of roots are more complicated. If we had, for example, to multiply $7\ 26'\ 43''\ 51'''$ by $11\ 47'\ 18''\ 56'''$, each term of one factor must be multiplied by every term of the other, and the denomination of each product must be as high as those of both factors put together. Thus when we come to $43'' \times 56'''$, the result must be in fifths ($2 + 3 = 5$); and 43×56 being 2408, we have 2408^{v}, or $40^{\mathrm{iv}}\ 8^{\mathrm{v}}$. This process was aided by a large sexagesimal multiplication table, which may be seen in Delambre, 'Astronomie Ancienne,' vol. ii. There is also a large sexcentenary table, constructed by John Bernoulli (III.), and published (or republished) by the British Board of Longitude. There is little need to give any further account of sexagesimal processes.

SEXTANS (the sextant), a constellation which Hevelius had the singular bad taste to place on the back of the Hydra and at the feet of the Lion. It comes directly between the bright stars α Leonis (Regulus), and α (or Cor) Hydræ. There are no stars of conspicuous magnitude in this constellation.

SEXTANT. The history of the sextant was involved in some doubt until the late Professor Rigaud undertook to investigate the subject. The result will be found in the 'Nautical Magazine,' vol. i., p. 351, and No. xxi. The following account is a brief outline of his inquiry.

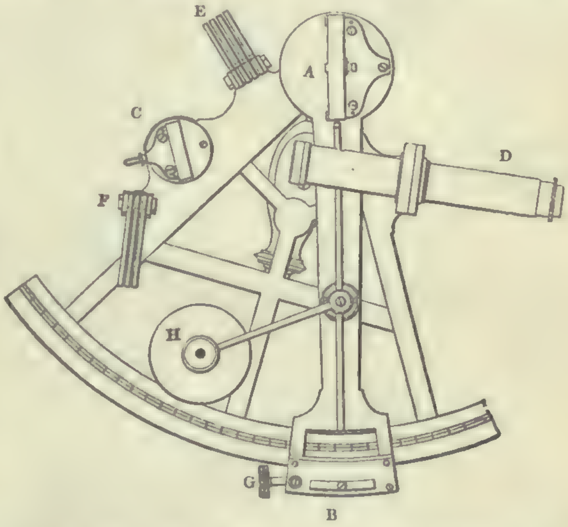
The early modern navigators used the *cross-staff*; this was afterwards exchanged for Davis's *back-staff*, called by the French *quartier anglais*. Hooke proposed an instrument for the purpose of taking altitudes at sea, which is very ingenious; the sun was seen reflected from a plane glass, while the horizon was viewed directly.* Hooke does not seem to have esteemed his invention so highly as it deserved; for in a subsequent lecture on astronomy and navigation, in 1694, he makes no mention of this, but describes a quadrant of a different construction. In 1699, Newton exhibited an instrument to the Royal Society, which is described as "the old instrument mended of some faults;" and at some later time he communicated to Dr. Halley a scheme for an instrument which was probably never executed, but of which a drawing and description were found among Dr. Halley's papers after his death in 1742. ('Phil. Trans.,' vol. xlii., p. 155.)

The date of the invention of Hadley's quadrant was proved, on examination by the Royal Society, to have been not later than the summer of 1730. A notice of it was given at a meeting of the society, May 13, 1731; and the instrument exhibited May 27. The memoir is published, vol. xxxvii., p. 147.

At the meeting of the society, May 20, Dr. Halley expressed an opinion that the principle of Hadley's new instrument had been discovered and proposed by Newton, and a search was made into the minutes of the society to ascertain the fact. The only notice which could be found was that already mentioned,—namely, in 1699,—and this was clearly an improvement of an old instrument, and not the proposal of one new in principle. Halley, at a meeting on the 16th of the following December, expressed himself satisfied that Hadley's instrument was much different from that formerly invented by Sir Isaac Newton. It seems not unlikely that Halley's recollections were of the instrument which Newton had proposed to him, and the description of which was found among his papers, but that he had forgotten the manner of the communication, and confounded the latter instrument with that which Newton had exhibited to the Royal Society. This is, we think, a very probable failure in the memory of a man of seventy-six, and what many younger persons experience daily. That Halley did not immediately see the advantages of Newton's latter proposal may appear a little strange; but Halley's forte clearly did not lie in mechanical construction or astronomical observation.

A little after Hadley's invention,—namely, about October or November, 1730,—Thomas Godfrey of Philadelphia, a glazier by trade, proposed and had executed an instrument which he called a bow, very much resembling Hadley's earlier construction. This was described in a letter to Dr. Halley from James Logan, Esq., dated 25th May, 1732. Mr. Logan had put off writing more than twelve months after the instrument was placed in his hands, and this neglect threw some doubt on the originality of the invention, which could only be satisfactorily established by additional evidence. After examination, the Royal Society came to the conclusion that Godfrey's discovery was also original. We think it is clearly proved that the priority is due to Hadley, and that there is no pretence for doubting Godfrey's originality. Some hasty writers, adopting mere hearsay for their guide, have attempted to give the subject a national and *patriotic* colour, which, unphilosophical at all times, is a simple absurdity when the contending parties are, as in this instance, of the same race. We have thus tried to give a hasty summary of Professor Rigaud's statements and conclusions, which we entirely adopt. The perusal of the original memoirs will gratify the lover of exact and discriminating research. Hadley's second construction, which is incomparably superior to his first and to Godfrey's bow, scarcely differs from the present sextant.

The sextant is figured and described in almost every book of navigation, and is so commonly to be met with that we shall be very brief. A is a plane glass, called the *index* glass, silvered behind, and perpendicular to the face of the instrument. It is fixed on a centre perpendicular to the instrument, and moves with the *index bar* A B, the end of which, B, slides over the graduated arc. C is a plane glass, the lower half of which, next the instrument, is silvered, and the upper half left clear. It is called the *horizon*-glass, and should be parallel to the index-glass when the index points to 0° at the beginning of the arc. D is a telescope for viewing the objects observed. This should be of good quality and with an inverting eye-piece. In the common quadrants there is merely a plate with a small hole for directing the sight. Suppose a ray of light to proceed from the eye, it will proceed in the direction of the telescope; and if it falls on the upper or unsilvered part of the horizon-glass, it will pass forward in a continued straight line until it falls upon some exterior object. But if the ray falls upon the silvered part of the horizon-glass it will be reflected to the index-glass (the horizon-glass is so placed as to make equal angles with lines from the eye and index-glass), and again reflected from the index-glass, outwards (that is, from the observer), until it meets some external object. Now instead of supposing the rays to pass from the eye, suppose them to come from external objects to the eye; then there will be two images presented at the same time, one formed by the rays which pass through the unsilvered part of the horizon-glass, and another formed by the rays which have been previously reflected by the two glasses; and it is easily shown from the elementary principles of optics, that when two objects are thus appa-



---

* This is described in Hooke's 'Posthumous Works,' p. 503, and was probably presented to the Royal Society in 1666. In practice, besides some other objections, it would have been troublesome to ascertain the *index error* in this construction.

rently seen in coincidence, the angle which they subtend at the point of meeting is exactly double the angle which is contained between the planes of the index and horizon glasses, if these be supposed to be prolonged until they meet. Hence, if the index be at zero when the glasses are parallel, and if the arc be divided into half-degrees which are numbered and subdivided as whole degrees, the arc actually read off, after any such observation as is here described, will measure twice the inclination between the glasses (for this inclination is evidently the same as the angle between the parallel position of the index-glass and its new position), and, in consequence of the optical principle above mentioned, this will be the true measure of the angle between the objects when they are so distant that the place of the eye and the intersection of the rays may be considered to be the same. The sextant, therefore, furnishes the means of measuring the angle between any two well-defined objects, in whatever direction they may be placed (so that the angle does not exceed 140°), and without requiring more steadiness than is necessary for seeing the objects distinctly. E and F are sets of dark glasses of varying intensity, which may be turned before either the index- or horizon-glass when required; G, a tangent-screw for giving slow motion to the index-bar; H, the reading microscope and reflector. The handle below is visible in the drawing, and there is a screw behind the collar of the telescope for giving an up-and-down motion to the telescope, which alters its distance from the plane of the instrument without affecting its parallelism thereto.

The adjustments of the sextant may be divided into those which more properly concern the artist and those which are to be attended to by the observer. It should be distinctly understood that no other instrument requires so much care and skill in its construction and use as the sextant. There are scarcely half a dozen makers in England, and probably not double that number in all Europe, who are fit to turn out a sextant; and though skilful sextant observers are somewhat more plentiful, they are still exceedingly rare. The fabric of the sextant should be strong and light. A blow which would not seriously damage a theodolet or circle, where three or more readings correct pretty nearly the errors which arise from such injury, would entirely ruin a sextant; but while giving strength, the maker must be on his guard to avoid weight. Troughton and Simms's double-frame sextants of 8 inches radius are a very good model, those of 10 inches are too large; single-frame sextants may be had of 7, 6, or 5 inches radius. All these sizes have or may have the same telescope, glasses, and shades. Those which we have hitherto seen seem to admit of some improvement in their scheme. Mr. Dollond casts his sextants in one piece of hard metal, which is an improvement, and very beautiful instruments they are. The limb of the instrument should be perfectly plane, and the axis on which the index-glass turns exactly perpendicular to it. If a purchaser is sufficiently confident in his own judgment to rely on that, rather than on the reputation of the maker, he should release the clamp, observe whether the index-bar moves easily and without shake along the whole arc, and also whether the vernier seems to press equally in every position. The telescope should be of the best quality, with a large aperture and of as short a focal length as these conditions permit. It should show the edge of the sun and moon quite sharp and distinct with the highest powers employed. The index-glass is generally the most faulty member of a common sextant; the faces are not parallel, and consequently when rays fall very obliquely upon it (in which case those reflected from the front surface are nearly as copious as those from the silvered back), there are two faint and separated images seen instead of one bright one. The artist tries his index-glasses by the following test: The sun is viewed with a high power after *very* oblique reflection from the index-glass, and those glasses only are retained in which the image is single and sharp. The rejected glasses find their way to the second-rate makers. The horizon-glass, which is smaller and on which the rays fall at a larger angle, does not, if imperfect, affect the images so much, but it too should be examined. The shades or dark glasses, which are either interposed between the glasses or placed before the horizon-glass, are next to be examined. The two images of the sun are brought into proper contact, after applying the highest power to the telescope and putting the proper dark glass on the eye end. One of the lightest shades is then interposed between the index and horizon glasses, and if the contact is slightly disturbed, this shows the form of the shade to be prismatic. The shade is turned in its cell until the effect is perpendicular to the plane of the sextant. The corresponding shade before the horizon-glass is now interposed and tried as the former one, and turned round exactly as before, until its effect is also perpendicular to the plane of the instrument. Leaving this latter shade untouched, and substituting the next dark shade in place of that first employed, the process is again repeated, with this caution, that the error, if any, caused by the prismatic form of the last shade, is to be made exactly contrary to that of the first shade, as well as perpendicular to the plane of the sextant. In this way, changing when necessary the dark glass at the eye end of the telescope, all the dark shades are carefully examined and set right, and it need not be said that those which are very prismatic or which affect the sharpness of the images, are to be rejected. The index-glass is now to be set at right angles to the plane of the instrument. This is done by looking very obliquely in the index-glass, when the edge of the limb or the divided arc seen by reflection will form an uninterrupted continuation to that seen directly, if the glass is perpendicular; otherwise the arc will appear broken where the direct and reflected images meet; by touching the screws seen in the figure, this error may be corrected. Repeating the observation at different parts of the limb, will show whether the axis has been set at right angles to the limb. The horizon-glass is to be made parallel to the index-glass by bringing the two images of the sun to coincide, when, if there is any lateral overlapping, it may be remedied by turning a screw (shown in the figure) which is in the mounting of the horizon-glass. The index error, as it is called, is of no importance whatever, though many observers are afraid that when large it vitiates the observation. This is an idle prejudice, but one which the maker is compelled to respect. Having ascertained the diameter of the sun by measuring it forwards and backwards, he sets the index to the proper angle and then files away a little of one of the pins against which the index-glass is pressed, until he brings the images nearly into contact. Contacts should now be formed, first by turning the tangent-screw so as to separate the images, and then by bringing them together. If the readings do not agree, the centre moves too stiffly or the index-bar is too weak. Finally, the telescope is to be set parallel with the plane of the instrument. There are two parallel wires in the focus of the telescope, which are to be placed parallel to the instrument, and then as large an angle as possible is to be taken between two distinct objects, making the contact exactly in the middle of the wires. The contact must now be examined when the objects are first at one side and then at the other of the field of view. If they separate equally when at equal distances from the centre, the position of the telescope is correct; if not, there are adjusting screws in the collar which carries the telescope by which this error may be corrected. For some of these latter adjustments mechanical means may be and sometimes are applied. The instrument should however comply with the foregoing tests, which any one can try who understands the use of the instrument.

We will now suppose an observer equipped with such a sextant, who wishes to make the best use of it. Before taking a series of observations, the index error should be ascertained. The telescope is fixed and set to focus, and the parallel wires placed parallel with the plane of the instrument. If the sun is visible, a dark glass for the eye-end of the telescope is selected, which shows him clearly, but without distressing the eye, and the direct and reflected images are made equally bright by moving the adjusting screw, which raises or depresses the telescope. The contact is first made, bringing the reflected image apparently below the image seen directly, and the angle is read off on the supplemental or back arc: suppose this reading to be 33′, which consider positive or +. Then make the contact again with the reflected image apparently above that seen directly (the reflected image is that which moves on moving the index), and read off again: suppose this is 32′, which call —. It is evident that at the middle position the two images coincide, and the index and horizon-glass are parallel; that is, the reading on the back arc is 30″ when the glasses are parallel. Hence 30″ must be *added* to every other reading to give the true angle. If the algebraical signs are used, the rule is very simple: Add the two readings together and halve the result; this with its *proper* sign is the *index correction* to be applied to all observations. If the sun is not visible, the moon may be used in the same way. If neither is to be seen, then bring the two images of a bright star, or the sea horizon, or any *distant* well-defined object into contact, and the reading, if on the back arc, is to be added, if on the forward arc, is to be subtracted from all other observations. The sun is always to be preferred when visible, and the observation is to be repeated before or after correction. If the images overlap laterally, that is, if the horizon-glass is not parallel to the index-glass, this must be previously adjusted. The next caution is with respect to dark glasses. When it is possible (as in observing altitudes of the sun at land in a mercurial horizon, &c.) to make the observation with a single dark glass on the eye-end of the telescope, without using any shade, this should always be done, for the error of this dark glass does not affect the contact at all, and the distortion caused by it is not magnified, whereas any fault in the dark shade between the index and horizon glasses produces actual error in the observation, and the distortion is magnified subsequently by the telescope. The images are to be brought to equal brightness by the screw which raises or depresses the collar carrying the telescope, and that with considerable nicety. In observing distances of the sun and moon, or altitudes of the sun at sea, dark shades are necessary. The fainter object is to be observed directly, and a proper shade interposed between the index and horizon glasses to reduce the two objects to something like the same brightness. The final equalisation is to be effected by the up-and-down motion of the telescope. The accuracy of the observation depends a good deal upon the nicety with which this equal toning of the two images is effected: with a little experience this is readily learned. From the construction of the sextant the faint object is easily viewed *directly* when the brighter object is either above or on the right hand of the fainter, but not so if the bright object is to the left of the fainter, when the handle side of the instrument is uppermost. For these observations, the instrument should have a second handle, which may be applied when wanted; perhaps when the distance between the moon and a bright star or planet is to be observed, there may be no difficulty in viewing the moon directly, after placing a dark shade before the horizon-glass, though the light which enters the eye without passing through the telescope must deaden the retina considerably. A blackened card screen slipped over the tube of the telescope would probably be found useful in this case, and absolutely necessary if the sun were observed directly. This latter observation cannot, we conceive, be satisfactorily made in any case. When the sextant is held in the hand, it should not be grasped tightly, as this causes tremor. The handle should be fitted to the observer's hand. There is scarcely ever hold enough given. When observing an altitude at sea, there is a little difficulty in bringing down the object to the point of the horizon immediately under it. But as the shortest distance is the true distance, by running along the horizon and keeping the object in the field, the direction in which the object should be observed is easily found, and the contact made there. In observing lunar distances the great art is to turn the instrument round the line of sight exactly as if the telescope were an axis of rotation. The index is set to the approximate distance, and the fainter object viewed directly; when the plane of the instrument passes through both objects, the brighter will come into the field, and the contact is to be made by the tangent-screw, or nearly so. We think it is better in all cases where the angle between the objects is increasing or decreasing, to make the contact open or close, and then try to seize on the moment when the contact is perfect, or the two moments when the contact begins and when you conceive it to end. The mean will probably be near the truth. All contacts must be made scrupulously in the centre between the two parallel wires. When the angle is large, inattention to this point will cause considerable error.

On shipboard, the observations, except those of lunar distance, are necessarily rude and imperfect, the sea horizon is generally ill defined and badly seen, the dip is somewhat uncertain, and as the single altitude is observed, all the error committed tells upon the final angle. The accuracy of observation is however equal to the wants of navigation in ordinary circumstances. (A *dip sector* might be useful where more than usual accuracy is required.) On land, where the altitudes are taken from a mercurial horizon, and the sextant fixed on a stand, the observation is capable of great accuracy, and does not require much skill or delicacy in mere handling. There is one peculiar advantage in sextant observations, that when the mercury is quiet enough to reflect a well-defined image, there is no need of any further steadiness or of a second observer, one of which conditions is absolutely necessary in every other instrument in common use which is adjusted by a plumb-line or level. We think the capabilities of the sextant as a geographical instrument have not been generally appreciated by English travellers; certain it is that few have used it with all the profit they might have done.

The mercurial horizon is a shallow rectangular wooden or iron trough, into which a small quantity of mercury is poured. If there is any wind, the trough must be covered with a penthouse, the sloping sides of which are glazed with plates of glass ground very flat and true. Any object seen in the mercury appears to be just as much below the horizontal plane as it is really above it; hence if the angle between any heavenly body and its reflection be measured, this angle is just twice the actual altitude of the body at that time above the horizon of the place. Suppose the altitude of the sun is to be observed in order to determine the time: The trough is placed with its largest dimension towards the sun, and the roof so that the sides cast no shadow, the proper dark glass is affixed to the telescope, the images brought to equal brightness, the index error ascertained, and the telescope is then directed to the image of the sun in the mercury. Holding the plane of the sextant vertical, and moving the index forward gradually, the image of the sun reflected by the index-glass will appear to enter the field from below. If the sun be rising, the index should be carried forward until the two images, having crossed, are clear of each other, and then the index is clamped. The two images will gradually close, and the exact moment by the chronometer is to be noted when the contact takes place. If the sun is rising with tolerable rapidity, the contact of the upper limb, that is, the separation of the two images, should be noted, exactly as before, without touching the clamp. The index is then read off; it may then be put forwards, and the observation repeated. If the interval between the contacts of the lower and upper limb is found to be in both cases nearly the same, the observer may be satisfied that he has committed no great error in noting the moments of contact. Where the greatest accuracy is required, it is usual to set the index to a whole number of degrees for the first pair of observations, and to put it forward 1° 30′ or 2° for the second pair, and so on till the observer is satisfied or wearied; and then in the afternoon to set to the highest reading for the first pair, and so on *backwards* till you arrive at the first reading. Collecting the corresponding pairs, you have an approximate time for apparent noon, which, after being corrected by the *equation to equal altitudes* for the change of the sun's declination, gives the time of *apparent* noon by the chronometer; and this, when corrected a second time by the *equation of time* taken and interpolated from the 'Nautical Almanac,' gives the time of *mean noon* by the chronometer, and consequently the error of the chronometer on mean time at the place. If the altitudes are very low, and the barometer and thermometer have changed considerably between the observations, a corresponding correction must be applied, but in most cases this is not requisite. The time may in this way be generally got as accurately as the chronometer will keep it during the interval. When observations of the sun are made for the latitude, the altitudes should be taken continuously for several minutes before and after apparent noon, observing the upper and lower limb alternately, or at least an equal number of each: thus getting rid of the sun's semidiameter, besides bringing more divisions into play. It is not easy to give a definite rule for the extent of these observations on each side noon; but when the time is known, and the altitude of the sun not great, we have never scrupled to go as far as the *Tables of Reduction*, that is, a good half hour on each side of the meridian. It is of great importance however, when the observations are pushed so far, that the number of observations on each side, and the times at which they are taken, should nearly correspond. If this precaution be observed, a slight error in the actual time of noon does not matter. When time is determined by absolute altitudes, the roof of the mercurial horizon should be reversed after half the observations, and the same precaution should be adopted when observations are made for the latitude. For equal altitudes it is necessary to keep the same position of the roof in both cases.

In the observations already described, and for lunar distances, a stand for the sextant will indeed add greatly to the accuracy of the observations, but is not absolutely necessary for a practised observer; so far as our own experience has gone, good observations of the stars can scarcely be made without a stand. By lying on the ground, and resting the edge of the sextant on a book or some convenient support, the observation may undoubtedly be made; but in most situations and in many climates this would expose the observer to more inconvenience and risk than he can prudently encounter. With a stand, and a little experience in setting it up, the observation of a star is just as accurate as that of the sun. The time is noted when the images form a figure like this **, parallel to the horizon; and stars of the third magnitude, or even lower, are quite bright enough for the purpose. We have observed Polaris very tolerably with a snuff-box sextant when the instrument rested on a book; the telescope, though of extra size for the instrument, was of much smaller aperture than those attached to ordinary sextants. It is rather steadiness which is required for these observations than light. Equal altitudes of the same star give the moment of its meridian passage by the chronometer without computation; and as this is the R.A. of the star, the error of the chronometer, if it be sidereal, is obtained at once; if it should be a solar chronometer, the computation is very easy, that is, merely computing the mean solar time of the star's transit of that day from the R.A. of the star and the longitude of the place. The computation of *circum-meridian* altitudes of a star for the latitude is rendered more simple by using a sidereal chronometer, for the hour angles observed with the solar chronometer must be reduced to sidereal time before taking out the corrections to the meridian from the Tables of Reduction.

There are certain faults either usual or inevitable in the sextant, which are now to be pointed out, and the mode of eliminating their effect from the final result. First, the determination of index correction is always somewhat erroneous, and this error runs through all the absolute observations, and affects the mean with its whole amount. Again, if the telescope be not parallel to the plane of the instrument, or if the contact be not made exactly midway between the wires, the angle read off is too large, and exceeds the true angle, and there is no principle of compensation; this class of errors has always the same sign. Finally, as sextants are now divided, there is no certainty that the axis of the index is exactly concentric with the divided arc. It is difficult to say within what limits this error is confined, but we think it amounts not unfrequently to 10″, 15″, or even 20″ in the total arc.[*] This is not, however, proportional to the arc, though it is generally smaller in the smaller arcs. Hence if this effect of excentricity lie the same way as the other errors, as it easily may, the most careful observer will make a considerable mistake in measuring a large angle. If we further suppose the error of the lunar tables to be in the same direction (the best meridian observations show that the moon is not unfrequently from 10″ to 15″ out of her tabular place), it will be seen that the longitude, determined as it generally is by distances between the moon and sun, or the moon and a *single* star, may differ much more from the truth than lunar observers usually think possible.[†]

Mere instrumental error is got rid of by combining those observations which they affect in contrary ways. Thus in equal altitudes, the *fixed* errors, such as index error, excentricity, bad division, inclination of the glasses or telescope, have contrary effects on the morning and afternoon sights, and therefore no effect on the mean. Making the contacts out of the middle of the wires is a casual error, and just as likely to happen in the morning as in the evening observations; so that as the angles are the same in both cases, errors of this kind will have pretty much the same influence on the mean of several pairs.

---

[*] Mr. Simms is of opinion that with a dividing engine of a better construction, this error of excentricity may be reduced to 2″ or 3″.

[†] We think no prudent seaman would rely upon lunar distances at sea to a smaller quantity than one-third of a degree. At land a good observer should seldom be out more than an eighth of a degree; and a large mass of careful observations, corrected for the errors of the lunar tables, might perhaps come within the sixteenth or twentieth of a degree. This seems to us almost the limit of what is to be expected from lunar distances, and it is inferior in accuracy to one favourable lunar transit, with a tolerable telescope, a well practised observer, and a corresponding observation at a principal observatory.

Hence the great excellence of the method of equal altitudes for determining the time, so far as instrumental error is concerned; it is an additional advantage that an error in the supposed latitude is also without sensible influence. Again, if time is deduced by absolute altitudes of a star rising in the east, the result will be affected one way by the errors above described; if a second star be observed at nearly the same altitude setting in the west, the altitude will be affected to the same amount; and if the stars have declinations which do not widely differ, the result deduced from the second star will be affected to the same extent, but in a contrary way from the first; a mean of the two results will be nearly free from any error, except the casual error of observation. A latitude by the sun or a star to the south, which is erroneous from the above-mentioned causes, will be balanced and corrected by a star of nearly the same altitude to the north; or a star to the north may be balanced by two to the south, one of higher and the other of lower altitude. It is scarcely credible how nearly the time or latitude may be thus determined. We have a series of such latitudes with an 8-inch sextant, observed by Mr. Lassell at Liverpool, which scarcely differ more than 2″ or 3″ from each other, though deduced from different groups of Greenwich stars. When the longitude is to be obtained from lunar distances, a considerable number of observations should be taken from the objects east and those west of the moon. If a pair can be selected on different sides of the moon, and nearly at the same distance from her, the result will be liable to the effect of casual error only, and to the error of the lunar tables. This latter error cannot be got rid of at the time of observation; but after the Greenwich, Cambridge, Edinburgh, Cape of Good Hope, and Oxford observations for the year have been published, it will generally be possible to find the error of the moon at the time of observation with considerable accuracy. This must be done whenever a sure longitude is to be deduced from lunar distances, and lunar observations must be taken in great numbers, so as to destroy casual error, to settle nice points in geography.

When a few more fundamental points in longitude are fixed, it will not be necessary to use lunar distances, except in long voyages, or in the centre of large and uncivilised countries. The recent improvements in chronometers, and the reduction in their price, have greatly superseded this kind of observation already, and will continue to do so more and more.

When the arc of the instrument is limited to 90°, which is usually the case in the common wooden instrument, it is called a quadrant (and sometimes an octant, as being in form an eighth of a circle), and a second horizon-glass and sight are sometimes appended for the *back* observation. A sight-vane (a plate of brass pierced with a small hole) is placed below the ordinary horizon-glass, and a second horizon-glass is fixed near this vane, so that lines from the centre of the index-glass, and from the latter vane, make equal angles with its plane. The plane of this second horizon-glass should be at right angles with the index-glass, when the index is at zero. This adjustment may be verified by making the sea-horizon seen directly through the second vane and unsilvered part of the second horizon-glass, coincide with the sea-horizon at the back of the observer, which is seen by two reflections from the index-glass and silvered part of the second horizon-glass. The angle between the fore and back sea-horizons is evidently equal to 180° + twice the dip of the horizon. The dip is known from the observer's height above the sea-level. Suppose it to be 4′, and that the reading on the back arc is 5′; it should be twice the dip, or 8′: therefore the zero position of the index for the back observation is at 3′ on the forward arc. This may be corrected by altering the second horizon-glass, if there are the means of adjustment; that is, by making the front and back sea-horizon coincide when the reading is 8′ on the back arc. By moving the index forward, the reflected sun, which is behind the observer, can be brought to touch the sea-horizon in front; and the reading, when the index error has been corrected, is 180° — the sun's distance from the front horizon. Now this latter angle is evidently 180° + 2 × dip — sun's altitude; hence it is clear the angle read off is the sun's altitude above the horizon — 2 × dip. Hence sun's altitude — dip (the altitude required) = angle read off + dip. If the index error be not adjusted, the angle must be corrected for the index error; in the preceding instance the 3′ must be added to the sun's altitude. The back observation, however, though useful in certain circumstances, is not much used at present, and many quadrants are fitted up without the second vane and horizon-glass.

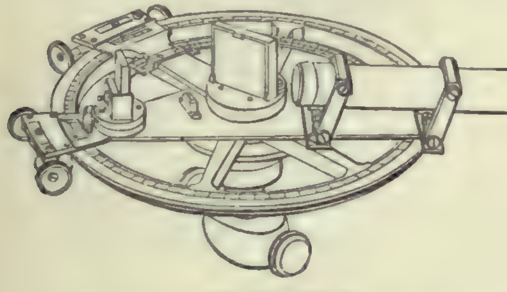
If a sextant be used in the manner we have attempted to describe, the results will be found to be very satisfactory. The attentive reader will see that the principle to be seized upon is that of always making two observations at nearly the same time, in which the errors, except the casual errors of making the contacts and of reading off, are the same, but the effects of which on the final result are different. It is not always convenient to afford the time which these balanced observations require; and, in fact, they are often impracticable. It will, therefore, be well worth the careful observer's while to determine the constant errors of his sextant, at different angles, where he has a good opportunity, and to use this knowledge where circumstances do not allow him to make a balanced set.

Very small sextants are sometimes fitted in a box, and are called *snuff-box* sextants. These admit of considerable accuracy; but, except in particular cases, they are not carefully adjusted, &c. The principle is, of course, the same as in the larger sextants, and they have a small telescope and dark glasses. It is desirable that the box should be wide enough to admit a finger to wipe the glasses, especially when the snuff-box sextant is used, as it frequently is, for maritime surveying. The salt spray very soon clouds the glasses, and there is no light to spare. For all sea-going purposes, except taking lunar distances, and for military and maritime surveying, the snuff-box sextant will be found very convenient and sufficiently accurate. If made with the utmost care, and skilfully used, we think it capable of determining the latitude within 1′, and the time to 3^s or 4^s; but an instrument-maker could not be expected to take so much trouble, unless for a favourite customer or for an expedition of some importance.

After the invention of Borda's repeating reflecting circle, Troughton, who was averse to the principle, produced a non-repeating circle, which he called the British circle; but it more commonly goes by his name. This may be understood by conceiving the circle, of which the sextant is a part, to be completed, and that while the telescope and glasses are at the front of the instrument, the divisions and three equidistant verniers attached to the index-glass are at the back. The observations ought always to be made in pairs, and for this purpose there are two handles, one to the front and another at the back. Thus, suppose it were required to take the altitude of the sun: this is first observed exactly as with the sextant, and the three verniers read off, the index-glass being above the line which joins the telescope and horizon-glass. Let the instrument be conceived to turn round this line through 180°, then the index-glass is below, and with the face downwards. By moving the index backwards to zero, it will become parallel to the horizon-glass, and continuing this motion until it is at the original angle, but *on the back arc*, the sun will be brought down exactly as in the former observation; when the contact is to be made with the tangent-screw, and the indices again read off. By combining the observations it is clear the index error is destroyed, and this is one point of superiority to the sextant. Again, the three readings wholly destroy any effect of excentricity, and very greatly diminish those errors which may arise from accidental injury to the figure of the circle, while the six readings greatly reduce the errors of division. The errors caused by defects in the dark glasses and horizon-glass are eliminated, and such as arise from a defect in the index-glass are diminished, and this too by the principle of the instrument, using it independently upon one object. These advantages are undoubtedly very great; but the additional weight of the circle and trouble in handling it, the trouble of reading three verniers for every observation, the shortness of the radius, and consequent necessity of limiting the subdivision to 20″, seem to overbalance them in the opinion of most seamen. We think that an intelligent observer will get results of nearly equal value from the sextant or from Troughton's circle, but that the sextant requires much care in selecting and balancing observations, which the circle does not. Whenever time or latitude is to be deduced from observations of one object at one time, as where the sun alone is used on geographical expeditions, or where lunar distances are taken from the sun alone, or from one star, the sextant cannot enter into comparison with the circle. A very excellent Spanish observer, Don J. J. Ferrer, determined the obliquity of the ecliptic with one of Troughton's circles more accurately than the Greenwich quadrant could do, at a time when that quadrant was still the principal declination instrument in the Royal Observatory. And if frequent reading off is not too great an objection, Troughton's circle may be recommended as the safer and more independent instrument, and as demanding less thought and care from the observer.

We have already, in the article REPEATING CIRCLE, described the original discovery of the principle by Tobias Mayer, and his first application of it. After Mayer had greatly improved the lunar tables, he proposed the following construction for measuring the angle between the moon and any other object with the greatest exactness. ('Tabulæ motuum Solis et Lunæ, auctore Tobias Mayer,' London, 1770.) The instrument is an entire circle, on the centre of which the index-bar turns, the index-glass being over the centre. The telescope and horizon-glass are fixed on a second bar, which also turns, but excentrically, on the same centre. The two bars can be clamped independently of each other, and each in any position, and there is an index or fiducial line to each, by which the divisions of the circle may be read off. Now, suppose a distance between the moon and sun to be required (the dark shades, &c., may be understood from what has been said on the sextant): First, having fixed the index-bar at zero, bring the horizon-glass to be parallel to it by observing the sun (as in determining index correction); then move forward the index-bar, and observe the distance between the moon and sun's nearest limbs, as with the sextant. If the angle were now read off, we should have the simple distance affected with the whole error of graduation, and obtain no advantage over the sextant. By moving the horizon-bar, bring the two glasses to be parallel exactly as before, and make the measure between the limbs of the moon and sun also as before, by moving the index-bar alone. The angle, if read off now, would be twice the angle required, but the errors of division and reading off would be only those which affect the first and last position of the index-bar. In this way the angle may be *repeated* as often as you please, until the bars have travelled once, twice, or even oftener round the circle; and it is evident that the errors of division and reading off are those at the first and last position of the index-bar, and those alone, which may be as inoperative on the measurement of the angle as the observer pleases or has patience for. This would seem a great advantage; but when Bird was ordered to make a circle on this model, the divisions were found to be so good that repetition added little to the accuracy of which a single observation was capable, and the fresh determination of a position of parallelism after every observation was too much trouble to be taken when not absolutely necessary. The reflecting circle of Mayer was not adopted in England, but great pains were employed in constructing and dividing the sextant, in which our artists were eminently successful.

In France it is probable that the art of instrument-making was at this time less advanced, and therefore the merit of Mayer's principle was more readily appreciated. The celebrated Borda, who was a seaman and navigator, first had an improved instrument on this construction made about 1775,[*] and published a full description of its form and use in 1787 ('Description et Usage du Cercle de Réflexion, par le Chevalier de Borda,' Paris, 1787), to which we refer the reader as a standard and classical work. The accompanying figure will explain Borda's instrument, though it is not precisely similar to that which he recommended.



Five-Inch Diameter.
Borda's Reflecting Circle, by Troughton and Simms.

The index-glass, with its bar, vernier, and tangent screw, and the excentric bar which carries the telescope, horizon-glass, with its vernier and tangent screw, require no explanation. The telescope has a parallel-ruler motion to bring the images to equal brightness, which is, we believe, Bird's construction. Borda holds his telescope by two ears, each of which can be raised or depressed separately, and he has a graduation for each, so as to move them equal quantities. Dollond, in his very beautiful repeating circles, has an up-and-down piece *above* the bar. The important and essential conditions of the repeating circle are, that moving one index shall in no way affect the other; that the clamps when fixed shall not be liable to move from looseness, bad balancing, or bad centering when the position of the circle is changed; and finally, that the axis of the index-glass and the collar on which the horizon-bar turns shall both be so true, and of such a length, that the motions of each bar are parallel to the plane of the divided circle. The same precautions must be taken as in the sextant in trying the index and horizon glasses, in placing the prismatic edges of the dark glasses up and down alternately, in setting the glasses perpendicular to the plane of the circle, and the telescope parallel to it: and it is scarcely necessary to add, that the directions given above for using dark glasses, equalising brightness, &c., apply to one reflecting instrument as well as another. The cells into which the dark glasses are inserted, when wanted, are seen between the two glasses and also in front of the horizon-glass.

On looking at Borda's circle as it is here represented, the opening of the angle between the two glasses is towards the spectator; hence an observer looking through the telescope would see an object directly in the line of the telescope, and some other object, call it A, which lies towards the spectator, by reflexion. Now suppose the index-bar to be moved through the position of parallelism and until the glasses make the same angle as before, but with the opening from the spectator, it is clear, first, that the angle read off between the first and second positions will be twice the original angle; and secondly, that the observer, still looking at the same object as before seen *directly*, will see by reflexion an object on his right hand (call it B), which makes the same angle with the axis of the telescope as A did, but on the other side. Now if we suppose the whole instrument to turn half round upon the telescope as an axis, it is evident that A will be seen exactly as at first, while the index-bar has been moved forwards twice the angle between A and the axis of the telescope produced. This is exactly the complete observation with Troughton's circle, and thus while we have got double the angle by two observations, we have got rid of index error, and have only two readings to which error of division and reading off can apply.[*] Now suppose the instrument to be returned to its original position, and, leaving the index-bar securely clamped, move the horizon-bar, which carries the telescope and horizon-glass, through the same angle and in the same direction as the index-bar has travelled. If the original object be again viewed through the telescope, and the contact between that and A perfected by the tangent screw of the horizon-bar, it is clear that everything is exactly as at starting, except that the index and horizon-bar have each moved over the divided circle exactly twice the angle to be measured. Let the operation which has been described be repeated, and everything will be as at starting, except that the indices will have moved over four times the angle, and it is evident that there is no limit to the number of repetitions except the will of the observer. So that, theoretically at least, the influence of bad division, bad centering, and bad reading off upon the final angle may be reduced below any sensible quantity. There is another very considerable advantage, namely, that there are only two readings off of each vernier † for any number of repetitions.

On looking at the figure again it will be seen that the rays of light which fall on the index-glass pass *between* the telescope and the horizon-glass, and there is a particular angle at which they pass through the horizon-glass before falling on the index-glass. This occasions some inconvenience, as the reflected image in that case is scarcely ever quite perfect, and if the sun be the reflected object, the interposed dark glass increases the imperfection. When Borda's circle is used in the hand for observing altitudes, the instrument is to be held alternately in the left and right hand for the crossed observations, but in taking lunar distances there is the same difficulty as in the sextant when the face is downwards. A handle with curved tube may however be applied pretty much as in Troughton's circle, and if it is fixed into a collar which turns on the centre, it may be kept out of the way of the telescope, &c. There is a part of this circle which, though not actually necessary, will be found of great convenience, the graduated semicircular arc which is attached to the horizon-bar. The index-bar, either by its edge or by a fiducial line, points out the reading on the semicircle, and shows 0 on each side when the glasses are parallel. By the help of this it is easy to set roughly to any angle on one side or the other, and thus save the trouble which nice setting would require, or seeking for an object, which is still more troublesome. In some circles two small pieces which slide easily can be fixed on this semicircle, and the proper opening is given by the touch alone, that is, when the index-bar just feels the stop. But there is always a risk of forcing a clamp which is supposed to be fixed, by the slightest touch, and therefore we prefer setting by a coarse-reading. As the chronometer must be noted and read off at every observation, there will generally be light enough for this purpose. Borda's original circles were much too large, and very weak and ugly. Six inches diameter seems to us quite sufficient for an instrument of this construction, which is intended to be used according to its principle. The telescope and glasses are nearly the same for all sizes, and the repetition reduces the errors of division and reading off so rapidly that we should prefer rather a coarse division, which is easily seen, to a fine one. A boldly cut division to 30″ would probably be best for general purposes; the circle should be as light as is consistent with strength, but the main points to be looked to are the independence of the index and horizon-bars, the truth and perpendicularity of the centerings, and the firmness of the clamps. Whether the want of balance in both bars, and especially the horizon-bar, is wholly innoxious, is a point of some doubt, otherwise there would seem to be no theoretical objection to a well-made repeating circle. Hitherto this instrument has not been much used in England. By some it may have been thought more troublesome than the sextant; it has generally been made too large and cumbersome, and perhaps prejudice may be added as one of the causes why it has not been properly valued. At the same time, though warm partisans of the repeating principle, we conceive that the results with a repeating circle will not be superior to those which *may* be attained by the sextant or by Troughton's circle when in the best hands; but it is more independent, requires less thought and care and skill than the sextant, and is neither so troublesome nor so cumbrous as Troughton's circle.

An alteration was proposed in Troughton's construction by Mr. Hasslar, director of the survey of the coast of the United States. The circle turns freely round the centre, and is clamped at pleasure either to the frame which supports the horizon glass and telescope, or to the index bar which carries the index glass. The arrangement is exceedingly ingenious, but we suspect that the clamping and unclamping must affect each other, notwithstanding the beauty of the workmanship They are also made much too heavy for the hand, and, considering the principle, unnecessarily so. Mr. Haslar employed them, we believe, in his survey, but we have not heard of their use elsewhere. The idea of a moveable or flying circle was probably taken from De Mendoza Rios, who proposed a flying vernier, as well as circle. ('Phil. Trans.' 1801, p. 362.) The complication of this construction, and the practical objections to it, were, we presume, fatal to its adoption; for we are not aware that it has ever been successfully used. In observing altitudes at sea, it is presumed that the horizon is always visible, which in hazy weather, or in dark nights, is frequently not the case. There have been several proposals for overcoming the difficulty by adapting a plumb-line or level to the sextant when required.

---

[*] Borda's alterations were apparently very simple: he drew the telescope back until its object-glass fell short of the index-glass, while Mayer's projected beyond it, and he carried the horizon-glass forward almost to the edge of the circle, which Mayer planted close before his telescope. Yet these slight modifications completely changed the instrument.

[*] Some observers use the repeating circle as a sextant. They change the readings from time to time by altering the position of the horizon-bar and determining the zero position of the index-bar. This mode of observing will undoubtedly tend to destroy errors of division and excentricity, but it is a complete sacrifice of the best qualities of a repeating circle. At any rate index error should be destroyed in the way we have pointed out, which would be some compensation for the reduced radius of the divided arc. Borda calls the pair *observations croisées*, or *crossed observations*.

† The index-vernier is usually read off and the horizon vernier neglected. Lieutenant Raper has pointed out the following use of the second vernier. Place the glasses parallel and read off both verniers; then if you wish to measure two angles rapidly, observe one by moving the index-bar, and the other by moving the horizon-bar. In observing altitudes of two stars in uncertain weather and in maritime surveying, this recommendation may be of great service. Let the greater angle be first measured by moving the index-bar, then the angle moved over by the index-bar is the greater angle, and the difference between this angle and that moved over by the horizon-bar is the less angle.

Several modifications, additions, and supposed improvements have been made in this class of instruments, but none of sufficient importance to require notice here. The sextant and circle, such as we have described them, are sufficient for the cases which practically occur; and without disputing the ingenuity and even utility of certain modifications in peculiar and exceptional cases, we believe that there is little to be gained by such alterations as have been hitherto proposed.

For reducing observations made with reflecting instruments, we must refer to the usual works on nautical astronomy. The tables of Thompson, or Riddle, or Inman, or Raper, will afford sufficient information. Borda's memoir, already mentioned, should be carefully studied by every one who proposes to use a repeating circle; and Troughton's article CIRCLE, in Brewster's 'Edinburgh Encyclopædia,' will be found of great value, especially as a guide to the circle known by his name. We have ventured very frequently to modify their opinions and directions, and the intelligent reader may decide for himself.

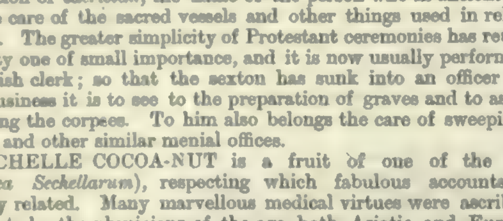
SEXTON, an officer of the church, whose name is supposed to be a contraction of *sacristan*, the name of the person who in ancient times had the care of the sacred vessels and other things used in religious services. The greater simplicity of Protestant ceremonies has rendered this duty one of small importance, and it is now usually performed by the parish clerk; so that the sexton has sunk into an officer whose chief business it is to see to the preparation of graves and to assist in depositing the corpses. To him also belongs the care of sweeping the church, and other similar menial offices.

SEYCHELLE COCOA-NUT is a fruit of one of the palms (*Lodoicea Sechellarum*), respecting which fabulous accounts were formerly related. Many marvellous medical virtues were ascribed to these nuts by the physicians of the age, both Asiatic and European, and they were consequently sold at a high price. At present they form only objects of curiosity, and are well-known under the name of double cocoa-nuts. To the inhabitants of the Seychelle Islands the tree is useful for its timber, which is hard externally, and employed in building their huts and for posts; the leaves and their footstalks are used for the roof, walls, and partitions, and for many other domestic purposes. The nuts weigh from 20 to 25 pounds each, and, when fresh, contain a white, transparent, and jelly-like substance, which is edible. The shells are employed in making vessels and dishes of various kinds, and the entire nuts form articles of commerce, as they are esteemed in other countries both for their fabled virtues and as curiosities.

SHADOWS, PROJECTION OF. [PERSPECTIVE.]

SHAGREEN. [LEATHER MANUFACTURE.]

SHAKE, in music, the alternate and rapid iteration of two sounds which are not less than a semitone, or more than a whole tone, apart. This grace—for as such it is considered—is generally introduced at a pause, and should commence rather slowly, and increase in rapidity as it proceeds, always concluding with a turn. Ex.:—

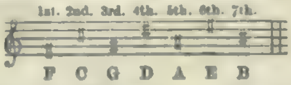


The *sign* of the shake is a *t* and an *r* conjoined, the two first letters of the Italian *trillo*, or the French *trille*, both signifying the same as the English term.

SHAKERS, a religious sect which arose in Lancashire about the year 1747. As the individuals of whom it at first consisted had previously been Quakers, they were sometimes called Shaking Quakers, but more commonly Shakers, from the violent shaking of their bodies in their religious exercises. In 1758 they were joined by Ann Lee, a native of Manchester, whose reputation gradually increased, together with the numbers of the sect, till, in 1770, she laid claim to divine inspiration, and called herself Ann the Word. In 1774, in consequence of the persecution to which they were subjected, she and some of her followers set sail from Liverpool for New York, where they arrived in safety. Ann Lee fixed her residence at Watervliet, on the Hudson, not far from Albany, and died at Watervliet in 1784. Their communities are called families. The property of each 'family' is held in common; and as the members, who are both males and females, are all single persons, celibacy being strictly enjoined, the numbers can only be kept up by converts. They are generally distinguished for good conduct in the common business of life. They agree with the Quakers in their abhorrence of war, their objection to take oaths, and in the belief of the direct influence of the Holy Spirit. Instead of the original violent shaking, they now move round their hall of worship in a regular and uniform dance to the singing of a hymn, clapping their hands in unison. There are some of the sect yet in Great Britain. No statement of the numbers of Shakers is given in the last census reports of either Great Britain or the United States; but several years ago there were said to be 6000 Shakers in the United States, comprised in fifteen 'families,'

SHAMOY. [LEATHER MANUFACTURE.]

SHARP, a character in music (♯), used to raise, by the degree of a semitone, any note in the natural scale. Before the character of the *natural* was introduced, the sharp was also employed to contradict the flat. When sharps are placed at the clef, they are always taken, according to the number required, in the following order:—



The DOUBLE SHARP, the character for which is a cross (×), is used in chromatic music, and raises a note two semitones above its natural state. Thus C *double sharp*

is, practically—though not strictly so in theory—D natural. [FLAT.]

SHAWL MANUFACTURE. The Hindoos have been the instructors of our manufacturers in the production of shawls. There are two modes of working the pattern in an Indian shawl; the one by embroidering it *upon* the material, and the other by working it *into* the web during the process of weaving. The first mode is a sort of needlework, and forms the less valuable kind of Indian shawl. In the production of the more costly kind, a number of skewers made of ivory or wood, about the size of a common packing-needle, are used; they are sharpened at both ends, and covered with different coloured wools. With these simple aids, the pattern is worked stitch by stitch into the web. The backs of these shawls show the effect of this minute and laborious handicraft, and present a totally different appearance from the European shawls, the patterns of which are woven entirely on the loom. These Indian shawls are mostly made from the inner hair of a goat reared on the dry cold table-land of Tibet, obtained after the long shaggy outer hair has been removed. No hair obtained from goats reared elsewhere has ever equalled this. Each goat yields about 2 lbs. per year. The best hair sells for 1 rupee per pound in Tibet. The wool is worked up into shawls in Cashmere, Lahore, and Delhi; especially the first named. Sometimes a sum equal to 300*l.* English will be given for a real Cashmere shawl.

Paisley excels all other towns in the United Kingdom in the manufacture of shawls, in quantity and (with one exception) in quality. The common kinds are woven in the power loom; while the finer kinds require the more detailed aid of the hand loom weaver. In the common shawls cotton is mixed with the wool; but for the finer articles the best wool of Germany, of Australia, and even of Cashmere, is employed. Some of the finest of these shawls are equal to anything produced in any other country. The Paisley weavers are mainly dependent on French patterns, which they modify in details; but the School of Design in that town is gradually training up a corps of designers whose taste may influence in an important degree the shawl manufacture.

The *printing* of shawls has not been much attended to until within the last few years; but now this art is carried to a very high pitch of excellence. At first it was adopted only for the commoner kinds of Scotch shawls. Red woollen shawls, printed in black designs for borders and centres, were at one time much in vogue. Then came imitations of them in cotton dyed Turkey red. Then chintz styles, upon white and light-coloured grounds. Next came in a fashion of printing the warp threads before the weaving. At length the manufacturers succeeded in producing blocks which would imitate the elaborate Cashmere pattern; this gave a great impetus to the printed shawl trade. Many establishments in Scotland now attend to this branch of manufacture, and strive to obtain new and good designs. The principal shawl-printing establishment in England is at Crayford in Kent, where as many as a hundred blocks, and sixteen hundred printings, or applications of the several blocks, have, in some instances, been necessary for the production of a single pattern. What an amount of labour is here involved, may be seen by referring to CALICO PRINTING.

SHEATHING. Owing to the great expense of copper sheathing, which has the effect of limiting its use in mercantile shipping, many attempts have been made to substitute for it either other metals, or alloys in which it is mixed with cheaper metals, or with such as might increase its durability. Mr. Robert Mushet directs that 100 lbs. of copper should be alloyed either with 2 oz. of zinc, 4 oz. of antimony, 8 oz. of arsenic, or 2 oz. of grain-tin; or instead of using one of these separately, that the whole be used together in the proportion of half an ounce each of the zinc and tin, 1 oz. of the antimony, and 2 oz. of the arsenic, to 100 lbs. of copper. By these mixtures, Mr. Mushet states that the copper is rendered much more cohesive and fibrous in its texture, and that the corrosive effect of the sea-water is in a great measure prevented. The metallic sheathing patented by Mr. Pope, consists either of tin and zinc, or of tin, lead, and zinc. If the former mixture be used, the zinc is first melted, an equal quantity of tin is added to it, and the alloy, after being stirred while fluid, is cast into cakes about three-quarters of an inch thick, which are hammered or rolled out to the required degree of tenuity. In uniting tin, lead, and zinc, the lead is first melted, double its quantity of tin is then added, and the alloy is cast into small lumps. A quantity of zinc equal to the tin and lead united is then separately melted, and the alloy of tin and lead is added to it; the whole, when thoroughly incorporated, being cast into cakes as before, for subsequent rolling out into sheets.

Iron, protected by the galvanic action of zinc, has also been used for sheathing. Mr. Pattison proposed to use sheets of iron similar in size to the sheets of copper sheathing, each having at its lower extremity a sheet of zinc from one-eighth to one fourth of an inch thick, attached in such a way that in sheathing the vessel from the upper part downwards, each succeeding sheet of iron shall be in contact with, and overlap, the zinc plate of the sheet immediately above it. Washers or perforated discs of zinc are also applied under the heads of the spikes or bolts used in fastening the sheathing; and the heads of the nails employed are made hollow, and filled with melted zinc.

Sheathing of brown paper coated with tar, and of various other non-metallic substances, has also been used. Perhaps the most important of these is a kind of felt, into the composition of which a considerable quantity of cow-hair enters. As this material itself felts very imperfectly, the sheets are passed, in the process of manufacture, through a boiler of pitch or tar, which increases the cohesion of the fabric. This material, which is sometimes used in conjunction with copper sheathing, being laid on immediately beneath it, has the important qualities of being a perfect protection against the worm, and of being at once impermeable to water, and so extensible as not to be easily broken by the working which takes place among the timbers of a crazy ship. A sheathing composed of a coarse fabric of fibrous material, saturated with a solution of caoutchouc, together with pitch and tar, has been recommended as a cheap and effectual substitute for felt.

Copper sheathing is usually applied in sheets about four feet long and fourteen inches wide, the thickness being such that a square foot weighs from sixteen to thirty-two ounces,—most commonly from twenty to twenty-eight ounces; and the mode of application does not vary materially whether the copper be laid upon the bare planking or upon an interposed layer of tarred paper, felt, or thin boarding. The sheets are pierced with holes, not only round the edges, but also at intervals of three or four inches over the whole surface; they are laid so as to overlap each other about an inch, and are secured to the ship with flat-headed copper-nails. Great regularity is observed in the arrangement of the sheets, so that a certain symmetry of appearance, as well as durability, is attained. After two voyages to the East Indies, or an equivalent amount of voyaging elsewhere, the coppering requires to be renewed; and the old copper is found to have lost three or four ounces of its weight in the square foot, by the action of sea-water, friction, and other causes.

All the copper sheathing for the Royal Navy—that is, for the ships built at the royal dockyards—is made at an establishment called the metal mills, in Chatham Dockyard.

SHEERS, or SHEARS, a contrivance used for hoisting the masts of a ship into or out of their place, and occasionally for loading and unloading heavy goods. The sheers used in masting vessels consist of two large poles, the lower ends of which rest upon thick planks laid along the sides of the deck; while their upper ends are lashed together so as to cross each other exactly over the hole in the deck through which the mast is to be dropped; they being sustained in this position by ropes radiating from the top to various parts of the vessel. To this apparatus is attached the tackle necessary for lifting the masts out of the water, when they have been floated to the side of the ship, and lowering them gently into their places. This is the apparatus commonly employed in masting merchant-ships; but the like operation is sometimes performed by means of a *sheer hulk* and sometimes by a *masting-house*. The *sheer-hulk* is an old man-of-war cut down to the lower deck, having a mast fixed in the hulk, and four stout spars or sheers which project obliquely from its side. The tops of these sheers reach to such a height and project to such a distance from the side of the hulk, that the vessel to be masted can come beneath them to be fitted with her lower masts. A *masting-house* is a lofty building erected for the purpose of performing the operation more conveniently, by the aid of mechanism overhanging the water to a considerable distance, beneath which ships may be floated.

SHEET-METAL. [COPPER; IRON; LEAD; TINNING AND TIN PLATE.]

SHEKEL (שֶׁקֶל), the principal weight and coin of the Hebrews. The subject of Hebrew weights and money is involved in great obscurity. The almost uniform testimony of ancient authors is that the shekel was equal to the Attic tetradrachm, or to the stater, or half the Roman ounce, that is to 4 denarii, which were reckoned at the period equal to four Attic drachmæ. The Septuagint indeed commonly renders the shekel by the didrachm current at Alexandria, which was double of the Attic. Hesychius, in one passage, makes it equal to four, and in others to two Attic drachmæ; and Suidas makes it five drachmæ. But the testimony of Hesychius and Suidas is of no value against that of St. Matthew, Josephus, Philo, and the other contemporary authorities. The average weight of the shekels of Simon Maccabæus is about 218 English grains, or half the English avoirdupois ounce, and only two grains more than the Roman ounce, or the weight assigned to the shekel by ancient writers. But the full weight of the Attic tetradrachm, to which the shekel is said to have been equal, was not the full one of 266 grains of the time of Pericles or Xenophon, but the reduced one under the Roman emperors, which was always considered as equivalent to the four denarii.

With respect to the shekel of the time before the Captivity, we have no certain information. The Rabbins say that after the Captivity all weights were increased by one-fifth; but there are many circumstances which prove this tradition to be of no value. In the absence of trustworthy information to the contrary, it is most probable that the ancient and the modern shekel were of the same weight, namely, about 218 grains.

The shekel formed the foundation of the Hebrew weights, of which there were three principal denominations: the shekel (שקל) meaning *weight*; the maneh (מנה), *number*, that is, a certain number of shekels or weights; and the kikkar (ככר), *a round number*, or *sum total*, that is, a certain collection of manehs, translated by the word "talent" in the Septuagint, Vulgate, and modern versions. The shekel, maneh, and kikkar corresponding respectively to the stater, mina, and talent.

The kikkar was equal to 3000 shekels. (Exod. xxxviii. 25.) There is a difficulty about the maneh, since from 1 Kings x. 16, compared with 2 Chron. ix. 16, it would seem to have contained 100 shekels, while in Ezekiel xlv. 12, it is ordered to contain 60 shekels. There are great difficulties in adopting the former value, and on the other hand the meaning of the passage in Ezekiel is very doubtful. If the latter value be adopted, the kikkar would contain 50 manehs. The shekel was subdivided into the beka (בקע, *half*), or half-shekel, or didrachm, the raba (רבע, *quarter*), or quarter-shekel, or drachm (the zuz or suza of the Talmudists), and the gerah (גרה, *a kind of bean*), or the twentieth of the shekel, or obolos. The following table therefore represents the Hebrew weights:—

Name	Value in Shekels.	Value in English Averdupois Weight.*		
		lbs.	oz.	grs.
Gerah	0$\frac{1}{20}$	0	0	10·94
Reba or Zuza . . .	0$\frac{1}{4}$	0	0	54·71
Beka	0$\frac{1}{2}$	0	0	109·43
Shekel	1	0	0$\frac{1}{2}$	
Maneh	60?	1	14	
Kikkar or Talent . . .	3000	93	12	

There appear however to have been at least two standards of the shekel, the *shekel of the sanctuary* and the *royal* or *profane shekel*. (Exod. xxx. 13; 2 Sam. xiv. 26.) The former was used in calculating the offerings to the Temple, and all other sums connected with the sacred law; the latter, for the tribute and civil payments. The tradition of the Rabbins is that the shekel of the sanctuary was double the profane shekel. By comparing the passages in Kings and Ezekiel quoted above, understanding the former of the profane shekel, and the latter of the shekel of the sanctuary, the process gives 100 : 60 or 5 : 3 for the ratio of the shekel of the sanctuary to the profane shekel.

The currency of the Jews from the earliest ages was silver, and this word expressed money. It is, however, nowhere mentioned as coined, but always as weighed out, till after the Captivity (Josh. vii. 21; 1 Kings xx. 39; Ezek. xlv. 15; Zechariah xi. 12), although some stamps appear to have been impressed on the ingots (Gen. xxiii. 16), or they were made up in the shape of rings, or *nezem* (Job xlii. 11, Septuagint). Gold money is first mentioned in David's time (1 Chron. xxi. 25; Isaiah xlvi. 6) under the name of אדרכון, *adarkon*, or דרכמון, *darkemon*, supposed to be gold darics, or drachms, neither of which however were in existence at the period, although both were probably current when the Chronicles were written or revised. The earliest Hebrew coins are the silver shekels of Simon Maccabæus, to whom the right of striking money had been conceded by Demetrius II, or Antiochus VII. (1 Maccab. xv. 6). These have on one side the supposed pot of *manna*, or, rather, gold and gemmed sacred vessel given by Simeon (1 Maccab. xiv. 15), with the legend שקל ישיאל, *shekel Ishrael*, "the shekel of Israel," and the initial letters of the year; and, on the other, the supposed Aaron's rod which budded, or, rather, the lilly of the valley of Israel (Isaiah xxxv. 1), and the legend ירישלים הקדישה, *Jerusalem haqodesha*, "Jerusalem the holy." The half shekels have the same types and legends, with *khatzi*, half, added to the word shekel. The inscriptions are in the Samaritan, and not in the square or Chaldee form, as it is called, of the Hebrew. No shekels of this dynasty are known later than the fourth year, after which the right of coining silver was suppressed, the Idumean line only issuing small pieces of copper; but there are later shekels of Barkozib or Barchochebas, who revolted under Hadrian, of broader and flatter shape, having on one side the wheatsheaf, or, rather, lulav, composed of palm, olive, and myrtle branches, with the legend ירושלם, Jerusalem, and on the reverse the beautiful gate of the temple, with four Doric columns and a star, allusive to the star of Jacob, with the legend שנת אחת לגאלת ישראל, *shenat akhat legulat Ishrael*, "the year one of the redemption of Israel," in a later form of Samaritan: these weigh 213·4 grains. The same Barkozib also recoined Roman denarii, for *rabas*, or quarter shekels, with a bunch of grapes on one side and the legend שמעון, Simeon, and on the other two trumpets crossed, or a lyre with לחרות ירושלם *lekharut Ishrael*, "the liberty of Israel."

It is as well to mention here that all pretended shekels or half shekels, with inscriptions in the square characters, are modern forgeries of the last two centuries, made by Dutch and German Jews for the purpose of deceiving the unwary collectors of ancient coins. According to the Rabbi Raschi the shekel was the same as the Tyrian of 24 obols or main, but St. Jerome (in Mica. proph. v. 14) makes the shekel equal to 20 obols, or 4 rabas of 5 obols each: 20 *geraks*, the supposed largest bronze coins of the Hebrew series, went to the shekel; and the gerah itself was subdivided into the *khatsi* or half, and *raba* or fourth, both of which expressions are found on the copper coins. There is a supposed third of a shekel, but it appears a nominal sum paid for the capitation tax, Nehem. x. 32, after the captivity. There is some difficulty in deciding upon what standard the shekel was adopted; the ancient Egyptian *kati* or *sati*, of 140 grs., by no means corresponds, and the Phœnician seems too heavy, although the weight is said to correspond with the tetradrachms of Antiochus VII. struck in Phœnicia.

If we assume that the standard was about the same as that of the Roman money, namely, $\frac{1}{30}$th of the weight alloy, the shekel of half an avoirdupois ounce would be equivalent to 210·983 grains of pure silver, or $\frac{210\cdot983}{80\cdot7}$ of a shilling, that is, to 2*s.* 7*d.* 1·49 farthings. According to this calculation, the following table represents the value of the Hebrew money:—

				£	s.	d.	farthings.
Gerah . . .	=	$\frac{1}{20}$ shekel	=	0	0	1	2·27
Reba . . .	=	$\frac{1}{4}$ „	=	0	0	7	3·36
Beka . . .	=	$\frac{1}{2}$ „	=	0	1	3	2·72
Shekel . . .	=		=	0	2	7	1·49
Maneh . . .	=	60 shekels	=	7	16	10	·8
Kikkar or Talent .	=	3000 shekels	=	396	5	10	

(Hussey, *On Ancient Weights and Money*; Winer, *Biblisches Realwörterbuch*, art. 'Sekel;' Calmet's *Dictionary*; Jahn, *Archäol. Bibl.*; Jennings's *Jewish Antiquities*; Cavedoni, *Numismata Biblica*, 8vo., Modena, 1850; De Saulcy, *Recherches sur la Numismatique Judaique*, 4to., Paris, 1854.)

SHELL, a hollow globe of iron, containing gunpowder, which is introduced at an orifice formed in the ball. In this orifice is driven or screwed the fuse or tube containing the composition by which the powder in the shell is ignited [FUZE]; and the shell, after being discharged from a gun, howitzer, or mortar, is consequently made to burst in pieces when it falls upon or near the object to be destroyed. The diameters of shells for guns vary from 3¾ inches to 10 inches, and the weight of a 10-inch shell is 70 lbs. The diameters of shells for mortars and howitzers vary from 4⅖ to 13 inches, and the weight of a 13-inch shell is 200 lbs. The diameters for carronades, which are now never used, varied from 3¾ inches to 8 inches. [BOMB; CASE-SHOT; SHRAPNEL-SHELL.] The shells for RIFLED ORDNANCE are described under that head.

SHELL-LAC. [LAC.]

SHELLS, *Economical uses of.* Shells are applied to several useful purposes, and to still more of an ornamental character. Some of them furnish dyes and pigments. The *purpura* contain an intense purple dye, in a few drops of liquid enclosed within a vein or sac in the fish. The *murex* yields various shades of purple and crimson. The *cuttle-fish* supplies the well-known sepia, of intense blackness. The beautiful substance called *mother-of-pearl* is described under PEARL FISHERY. The large proportion of lime in many shells renders them useful in making cement, and also as a fertiliser in agriculture. Shell-sand, produced by the natural crumbling of shells on the sea-shore, gives moderate fertility to many spots otherwise barren. Ground cockle and mussel shells are sometimes used as a covering for gravel walks. *Cowry* shells, inexhaustibly abundant on the shores of Asia and Africa, are used in India for the purposes of money, at an average value of about 200 for an English penny. The same cowries may be converted into a glaze for earthenware, and an enamel for clock-faces. A calcareous spongy plate found in the cuttle-fish is used by workmen as a substitute for emery-paper or sand-paper. The *conch* shell is in some countries used as a horn or trumpet; as in the West Indies, where on some plantations the negroes are summoned to work by a "conch-blow." The *haliotis* has an iridescent surface which fits it for use as a substitute for mother-of-pearl in inlaid work. The *helmet* shell supplies pieces large enough for umbrella-handles; and thinner portions as ornaments for workboxes and other trinkets. Smoked films from oyster-shells are used for large coat-buttons. The *clam* shells, often of very large size, are used in Roman Catholic countries as receptacles for holy-water; while some, perfectly white, are cut up for arm-rings and other ornaments. The fibres with which many kinds of shell-fish attach themselves to rocks, such as those of the *pinna*, are fine and strong enough to be worked up in the manner of silk. The *chank* shells of India are cut up into bangles, armlets, bracelets, anklets, finger-rings, toe-rings, &c., sometimes carved and gilt, or otherwise decorated. The fishery of chank shells, off Ceylon, is a very valuable one; seeing that some of the choice specimens are valued at their weight in gold. [CEYLON, in GEOG. DIV.] *Shell cameos* are noticed under CAMEO.

Considered as a working material, all shell is placed in one or other of two categories, *porcelanous* or *nacreous.* The porcelanous shells contain much lime and little animal matter; they are brittle, translucent, smooth, and not easily cut, and much resemble the enamel of teeth. They can only be worked on the lapidary method, with small grinding wheels. The nacreous shells, partaking of the nature of mother-of-pearl, contain less lime and more animal matter; they are tougher, softer, and iridescent; they may be easily sawn, scraped, and filed; and can then be polished with sand or pumice and water. [LAPIDARY WORK.]

SHERBET, as made in Persia, Turkey, and other eastern countries, is a beverage composed chiefly of water, lemon-juice, and sugar, with the addition of other ingredients to render it more pleasant to the taste; such as the pulp of fruits, perfumed cakes, amber, rose-water, &c.

SHERIF, an Arabic word which means "noble, illustrious," and a title given throughout Arabia, Egypt, and Barbary, to those who are descended from the Mohammedan prophet. In Turkey they are called amirs, that is, princes, and enjoy great privileges, such as not being subject to the payment of taxes; not being obliged to appear before a judge, unless he be one of their class; wearing a green turban and slippers; occupying a superior place in the mosque, &c. As men and women of this caste often contract marriage with persons who are not members of the same, and the title of sherif is inherited from either of the parents, the number of persons who enjoy this distinction has become very considerable in Turkey, Syria, and Egypt, where they may be found employed in the lowest offices. It is one of the privileges of Mecca to be governed by a sherif of the posterity of Hasan, son of Ali Ibn Abí Talib, which family enjoys the sole right to the throne. His dominions comprehend, besides the capital, Mecca, Medina, Jambo, Tayif, Sadie, Ghunfude, Hali, and thirteen other smaller districts, all situated in the Hejáz. His principal revenue consists of a tax imposed upon every pilgrim, and the presents made by Mohammedan princes.

SHERIFF, the Shire-Reve (scyr-gerefa), from the Saxon word *reafan*, "to levy, to seize," whence also greve. The German word is *graf*. The gerefa seems to have been a fiscal officer. In the Saxon period he represented the lord of a district, whether township or hundred, at the folkmote of the county; and within his district he levied the lord's dues, and performed some of his judicial functions. (Palgrave, 'Rise and Progr.,' i. 82.) He was usually not appointed by the lord, but elected by the freeholders of the district; and (accompanied by four of them) was required to be present on its behalf, as well as on the lord's, at the folkmote or county court. In like manner the Saxon prince or king employed in the shires or larger districts his gerefa or reve, who levied his dues, fines, and amerciaments; to whom his writs were addressed; who exercised on his behalf regal rights in the shire, for the preservation of the peace and the punishment of offenders; presided over the courts-leet or views of frankpledge, and (at least in the absence of the earl in ancient times, and since the Conquest instead of the earl) presided over the hundred and county courts. It is difficult to determine how far the functions of the sheriff were concurrent with and how far derived from the ealderman or earl of Saxon and Danish times; and the confusion between these offices has been increased by the translation, in our ancient laws, of the word sheriff in the Latin into *vice comes*, and in Norman French into *visconte* or *viscount* (deputy of the earl); whereas certainly many of the sheriff's powers even in Saxon times were derived from the freeholders, or from the crown alone, and the word graf (gerefa) in German was equivalent to our earl. That before and for a century after the Conquest the sheriff had powers independent of the earl, is obvious from the fact, that in the circuit (tourn) which he made periodically (Spelman's *Gl.*, 'Vice Comes') of his shire for the administration of justice (as the Saxon king made a circuit of his realm), he was accompanied not only by the freeholders, but by the bishop, the earl, and barons, until these noblemen were exempted from the duty by statute 52 Henry III., c. 10, A.D. 1267.

Sometimes the shrievalty, by grant of the crown, was hereditary; it was also often held for life, or for many years, and there were sometimes more sheriffs than one in a county, the persons chosen for the office being, according to Spelman, "totius regni proceres:" but the sheriff was usually chosen by the freeholders of the shire. The statute 28 Edward I., c. 8, which says that "the king hath granted unto his people that they shall have election of their sheriff in every shire (where the sheriff is not fixed in fee) if they list," is rather declaratory of the people's right than a grant of a new privilege. By the 14 Edward III., c. 7, it is enacted that no sheriff tarry in his bailiwick more than a year, and then another, who hath land sufficient in his bailiwick, shall be ordained on the morrow of All Souls, 3rd November, by the chancellor, treasurer, and chief baron of the exchequer, taking to them the chief justices of either bench if they be present. This was the law also, till quite recently, regarding under-sheriffs; but it has now been altered.

At present the crown in most cases appoints the sheriffs, and also fills up any vacancy which is occasioned by the death of a sheriff during his year of office. To some corporations of cities which are counties of themselves charters have given the power to elect their own sheriffs; the city of London has the right to elect the sheriff of Middlesex. In the county of Durham the bishop was sheriff until he was deprived of palatine powers in 1836; and in Westmoreland the office was hereditary in the family of the earl of Thanet as heir-general of the Viponts, to whom the shrievalty was granted by king John, until the death of the last earl, when it lapsed to and was subsequently by statute vested in the Crown. The annual appointment of sheriffs is now, in most counties, made thus:—On the morrow of St. Martin (12th November), the lord chancellor, first lord of the treasury, and chancellor of the exchequer, together with all the judges of the three courts of common law, meet in the exchequer chamber, the chancellor of the exchequer presiding. The judges then report the names of three fit persons in each county, and of these the first on the list is chosen, unless he assigns good reasons for exemption. The list thus made is again considered at a meeting of the Cabinet held on the morrow of the Purification (3rd February), at the president of the council's, and attended by the clerks of the council, when the excuses of the parties nominated are again examined, and the names are finally determined on for the approval of the queen, who, at a meeting of the privy council, pierces the parchment with a punch opposite the name of the person selected for each county; and hence has arisen the expression of "pricking the sheriffs." The judges of assize annually add the requisite number of names to their lists by inserting those of persons recommended by the sheriff going out of office.

The sheriff derives his authority from two patents, one of which commits to him the custody of the county, and the other commands the inhabitants to aid him. He takes an oath of office, the greater part of which relates to his collection of the crown revenue, and he gives security to the crown that he will duly account. He then appoints an under-sheriff, by whom in fact the duties of the office are performed. These duties are various and important. Lord Coke quaintly says that the sheriff has a triple custody—1st, of the *life of justice*, because to him are addressed the writs commencing all actions (all of which are now abolished), and he returns the juries for the trial of men's lives, liberties, lands, and goods; 2ndly, of the *life of the law*, because he executes judgments of the courts; and 3rdly, of the *life of the republic*, because he is in his county the principal conservator of the peace. By Magna Charta he is prohibited from holding pleas of the crown. He presides at all elections of members of parliament and coroners, and hence he cannot during the year of his office be elected a knight of the shire. He apprehends all wrong doers, and for that purpose, in criminal cases, he is entitled to break open outer doors to seize the offender; he defends the county against riot and rebellion or invasion [LORD LIEUTENANT], and to this end may require the assistance of all persons in it who are more than fifteen years of age, and who, when thus assembled under the sheriff's command, are called the *posse comitatûs*. [POSSE COMITATUS.] To refuse to the sheriff the aid which he requires is an offence punishable by fine and imprisonment. The sheriff takes precedence of all persons in the county. He seizes all lands which have fallen to the crown, and levies all fines and forfeitures; but he is not permitted to act as a justice of the peace. He executes many of the writs that issue from the superior courts, and all writs of execution; he is likewise responsible for the execution of criminals. He receives and entertains the judges of assize, on whom he is constantly in attendance whilst they remain in his shire.

To assist him in the performance of his duties, the sheriff employs an under-sheriff and also a bailiff and jailers, from whom he takes security for their good conduct. He is prohibited by very ancient statutes from selling his office or the profits of any part of it.

The liability of the sheriff for breach or neglect of his duties is a frequent sort of litigation. Few assizes occur without actions being brought against him for illegal arrests or levies, or for wrongfully abstaining from executing the process addressed to him. Thus the decisions affecting him are numerous and complicated, and there are many treatises concerning the office.

SHERIFF (SCOTLAND). In Scotland the duties of the sheriff are not, as in England, almost entirely executive. He exercises an extensive judicial authority, and a large portion of the general litigation of the country proceeds before this class of local judges. In earlier times his authority appears to have been merely of an executive character, and, appointed by the crown, he was the person to whom the royal writs, issuing from the supreme courts, were usually directed. He was the ordinary conservator of the peace within the local limits of his authority. He was an important fiscal officer, having in the general case the duty of levying the feudal casualties, forfeitures, and other items of revenue; and by statute he was vested with the power of mustering the military force of the country to the weapon-showing. In very early times, his tenure of office appears to have been limited by the grant; at a period comparatively later, the office became, in the general case, hereditary. The act for abolishing heritable jurisdictions in Scotland (20 Geo. II., c. 43), was passed for the purpose of abolishing all those remnants of the feudal courts of Scotland which were hereditary, or in any other shape of the nature of property; of bringing all judicial offices within the appointment of the crown, and their holders under responsibility to the public. By the same statute, the sheriff is authorised to appoint one or more substitutes; and at the present day there is a substitute in every county, and in the larger counties there are two or more. Both the sheriff and his substitute are lawyers, but the latter is the local resident judge, the former generally frequenting the courts in Edinburgh, where he hears appeals from his substitute, and making occasional visits to his county. By the Jurisdiction Act it was provided that each sheriff should reside in his county during four months in each year; this provision fell into desuetude, until by the 1 & 2 Vict. c. 119, it was enacted that each sheriff should remain in attendance on the court of session, but should hold eight courts in his county during the year. The sheriffs of Edinburgh and Lanark are exempted from attendance on the court of session, in the understanding that the business of their respective courts is sufficient fully to occupy their time.

In civil questions an appeal lies from the sheriff-substitute to the sheriff, but wherever the former is a sound lawyer and an industrious man, the privilege is seldom used. From the state in which the profession of the bar of Scotland has been for many years past, several of its members have been induced to accept the office of sheriff-substitute as vacancies have occurred. Formerly the office fell to country practitioners, who, not quite contented with the emoluments, eked them out by private practice; a state of matters seriously detrimental to the equal administration of justice. In some instances, even retired officers in the army or unprofessional country gentlemen were the best qualified persons who would undertake the office. No sheriff-substitute can now act as a law-agent, conveyancer, or banker; he is not removable, except with the consent of the lord president and lord justice clerk of the court of session, and must not be absent from his county more than six weeks in one year, or more than two weeks at a time, unless he obtain the consent of the sheriff, who must then act personally or appoint another substitute. In one or two instances, as in that of Kirkcudbright, the person who exercises the function of sheriff is called the Stewart. This designation owes its origin to certain peculiarities of territorial tenure which cannot be briefly explained and are subject to doubt and dispute. After the Reformation, the sheriffs were generally appointed commissaries of the local commissariat districts which most nearly conformed with their respective jurisdictions, and in 1823 (4 Geo. IV. c. 97) the commissariat functions were appointed to be merged in those of the sheriff.

The jurisdiction of the sheriff in civil matters does not extend to questions regarding heritable or real property. He cannot judge in actions which are declaratory of rights, or which are of a rescissory nature—for the purpose of nullifying deeds or legal proceedings. In other respects his jurisdiction extends to all actions on debt or obligation, without any limit as to the importance of the interests involved. He has also the same bankruptcy jurisdiction as the Court of Session. He does not act by a jury, though it appears that such an institution was formerly connected with the civil jurisdiction of the sheriff. He has authority by special statute summarily to decide small debt cases, that is, cases where the pecuniary value of the matter at issue does not exceed 12*l*. By railway statutes and other acts of local administration special functions are frequently conferred on him, and in the clauses for taking lands he is usually appointed to act as presiding judge when a jury is appointed to be empannelled. The decisions of the sheriff, when no proceedings have been taken to enforce them, may be carried into the Court of Session by advocation.

The authority of the sheriff in matters criminal is practically to a great extent measured by the proceedings of the crown lawyers in leaving prosecutions to proceed before his court, or removing them to the Court of Justiciary. It is not very clearly to be traced how far, in old practice, the sheriff's jurisdiction was inferior to that of the Court of Justiciary: he had undoubtedly the power of punishing with death, though it has been long disused. The power of transporting, which is of comparatively late introduction, he never possessed, not having any criminal authority beyond his county. By degrees it came to be considered that the jurisdiction in the four pleas of the crown—murder, rape, robbery and wilful fire-raising—was exclusively in the higher court. Important criminal cases in the sheriff court are tried by jury. In more trifling matters the sheriff performs the functions of a police magistrate. In these cases the punishment must not exceed a fine of 10*l*. or sixty days' imprisonment (9 Geo. IV. c. 29).

SHEW-BREAD (לֶחֶם פָּנִים), *lechem-panim*, "bread of faces," or, as it has been rendered, "presence bread," was the name given to the twelve unleavened loaves of bread, one for each of the tribes of Israel, which were constantly displayed on a golden table in the holy place of the Tabernacle and Temple. They were made of the finest wheat flour, and laid on the table in two similar piles, with frankincense and salt put over them. Every Sabbath they were renewed, and the old loaves were eaten by the priests in the holy place. The frankincense which was placed upon the shew-bread constituted it one of the "offerings made by fire to the Lord." The golden table on which they were placed was called the table of shew-bread. Wine was also placed upon it, and it was furnished with gold dishes, bowls, and spoons. None but the priests were permitted to eat of this bread; yet David, when in great need, ate of it, and incurred no blame.

SHIELD was a part of the ancient armour designed to ward off the strokes of the sword and all kinds of missiles. Shields were borne on the left arm, and were of different forms and sizes, and they were accordingly designated by different names. The large circular or oval shield, the invention of which was ascribed to Prœtus and Acrisius of Argos, was called in Latin *clypeus*, and in Greek *aspis* or *sacos* (ἀσπὶς or σάκος). A smaller kind of round shield was called *parma;* and a smaller kind of oval shield was called *pelta*. *Scutum* was properly speaking a square or oblong shield. The ancient writers, however, do not always accurately distinguish these different shields, but apply the name which properly denotes a particular kind of shield to shields in general. The shields in the earliest times were made of osiers twisted together (γέῤῥα), or of wood, and this framework was covered with the skins of oxen, of which there were mostly several layers, one over the other, whence Homer frequently calls the shield "seven-hided" (ἑπταβόειος). Xenophon ('Anab.,' i. 8) describes the Egyptians, even of his time, as using wooden shields. The whole rim was surrounded with a metal edge. In the centre of the outer or convex side there was a projection called the *ómphalos* (ὀμφάλος), or *umbo*, in which sometimes a spike was placed, which served as a weapon of attack against an enemy who approached too near. The object of the umbo, however, was to make the missiles glance off from the shield. In the inner or concave side there was a band of metal or leather, which went from rim to rim as a diameter, and under which the arm of the soldier was placed, so that the shield hung on the arm. Around the inner edge there was a number of small thongs, by means of which the shield was managed with the hand. The shields of distinguished persons, even as early as the time of Homer, were covered with metal plates, and frequently adorned with embossed figures. These figures were often of exquisite workmanship, as may be inferred from the descriptions of the magnificent shields of Achilles and Hercules in Homer and Hesiod. The shields of horsemen were generally smaller than those of the foot soldiers. The use of shields continued from ancient times throughout the middle ages, until they were made useless by the introduction of fire-arms.

The shields of individuals, as well as of whole divisions of an army, had sometimes particular devices relating to memorable events in their history, and these are generally supposed to be the first traces of the armorial bearings of more modern times. The numerous specimens of shields show that the knights of the middle ages were no less fond of adorning them with embossed figures, precious stones, &c., than the ancients. [ARMOUR.]

SHIFTING USES. [USES.]

SHIITES is the name of a sect among the Mohammedans. The word comes from *shiah*, "a faction, party, or set of men who separate themselves from the rest of the community," and who entertain religious opinions contrary to those of the *Sunnites*, or people who belong to any of the four orthodox sects of Mohammedanism. The name of *Shiites* is principally used to designate the sectaries or adherents of Ali Ibn Abi Tálib, who maintain him to be the lawful khalif and imám, and that supreme authority, both in spiritual and temporal matters, belongs to his descendants.

The Shiites are divided into numerous sects, of which the principal are: the *Imámians*, or those who believe that the office of imám, or head of the church, is not dependent on the will of the people, and that religion consists solely in knowing who is the true imám; the *Zeydians*, so called from the name of their founder, Zeyd, son of Ali, surnamed Zeynu-l-abadin (the ornament of the servants of God); the *Khattabians*, or disciples of Abú-l-Khattáb, who maintain that paradise is no other thing than the pleasures of this world, which God grants to those with whom he is pleased: hence their indulgence in wine, music, and other things forbidden by the prophet. The Persians are Shiites, and the Turks Sunnites: hence the cause of the schism still subsisting between them, which has been maintained on both sides with ardent zeal and implacable hatred. The chief points wherein they differ may be reduced to three:—1. The Shiites reject Abú Bekr, Omar, and Othmán, the first three khalifs, as usurpers and intruders; whereas the Sunnites respect them as rightful imáms. 2. The Shiites prefer Ali to Mohammed, or at least look upon him as his equal in every respect; whilst the Sunnites admit neither Ali nor even any of the prophets to be equal to Mohammed. 3. The Sunnites receive the *Sunna*, or body of traditions concerning the prophet, as of canonical authority; the Shiites reject it as apocryphal and unworthy of credit.

SHIP. The ships of war employed at first by the maritime nations of modern Europe were galleys, moved either by wind or oars, and were similar, probably, to those of the Greeks and Romans. In the beginning of the 15th century, vessels of a like kind, but of greater dimensions, constituted portions of the navies of France and Spain; they were called Carraques, and it is said by a French author of that age that the English ships scarcely dared to approach them. The term Galeasse was afterwards applied to a kind of war galley which was of greater length in proportion to its breadth than those generally constructed; its rowers were covered by a narrow deck running along each side of the vessel, and on this small cannon were mounted. Such were the vessels used by the Venetians at the battle of Lepanto.

Before the reign of Henry VII. the naval force of this country consisted only of the vessels furnished at short notices by the Cinque-ports, besides such as were hired from English or foreign merchants; and, according to Du Bellay, some of the ships were a sort of long galleys called Ramberges, in the management of which the English mariners are said to have been very expert. Henry VII. caused to be constructed the Great Harry, the first ship which can be ranked as one belonging to the royal navy of England; and his successor, in 1515, in emulation of Francis I., who had built a ship called the Caracon, carrying 100 guns, caused one of equal burden (about 1000 tons), and carrying 122 guns, to be constructed. This was called the Henry Grace de Dieu. It appears to have been built rather for magnificence than use; not more than 13 of the guns were 9-pounders or upwards; and its construction must have been very defective, for it is said to have steered badly and to have rolled incessantly. After having made one voyage, it was disarmed at Bristol and suffered to decay. The French ship was equally unfortunate, having been accidentally destroyed by fire at Hâvre. Henry VIII. exerted himself, however, to place the maritime force of the nation in a train for being improved, for which purpose he organised the Admiralty and Navy Boards, and formed dockyards at Deptford, Woolwich, and Portsmouth. [NAVY, BRITISH.]

During the reigns of Edward VI. and Elizabeth the royal navy became very powerful, and at the death of the queen it consisted of 42 ships of war. In the time of James I. was built (1610) a ship called the Prince, carrying 64 guns, and of 1400 tons burden, being the largest which had been till then constructed. And before the civil war broke out, Charles I. caused to be built one called the Sovereign of the Seas, which carried above 106 guns, small and great; her length was 128 feet, and her breadth 48 feet.

The ships of that age, foreign as well as English, were constructed with hulls extravagantly high, while the lower guns were frequently not more than three feet above the water; they were consequently very liable to ship seas at the lower ports during an action, when the waves ran high, or the ship heeled considerably. But the rivalry between England and the United Provinces in the 17th century, and the desire which Louis XIV. entertained to raise the navy of France to an equality with those of his neighbours, led to the construction of ships capable of carrying artillery of much greater calibre than had before been used at sea. The French king actually caused to be built at Toulon a ship called the Royal Louis, which carried 12-, 24-, and 48-pounders on its upper, middle, and lower decks respectively. In the same age, and during the 18th century, naval architecture was zealously studied in France; and the English constructors were so sensible of their inferiority, that in most of the ships built in England at that time the proportions were copied from those of ships which had been taken in action from the rival nation. Thus the Leviathan was built at Chatham nearly in conformity to the Courageux, a French 74-gun ship; and several others according to the construction of the Invincible, which had been taken by Lord Anson during the Seven Years' War.

During the 17th century the custom continued of giving to the sterns a great elevation above the surface of the water, and of loading that part, as well as the bows, with ornaments. The sterns of ships of war were, till about forty-five years since, made, at their junctions with the sides, of an angular form, or, as they were called, square; and before 1729 they had projecting galleries or balconies extending across them, and to some distance along each after-quarter of the ship. The galleries were afterwards much diminished in breadth; but it was not till 1796 that, by the influence of Lord Spencer, who was then the first lord of the Admiralty, these, as well as the great projecting heads, were entirely omitted in the construction of ships. In 1816 Sir Robert Seppings' proposed to make the sterns curvilinear like the bows, but more flat; and by the adoption of his plan there was gained considerable strength, such a form enabling the ship to resist with great effect the force of a sea in striking the stern, and that of shot when fired against it. With respect also to the means of defence at the stern and quarters of a ship, it may be observed that the curvilinear stern has greatly the advantage over those of an angular construction, there being in the angular an interval opposite each quarter of the ship towards which none of the after-guns can be brought to bear, while such interval does not exist in the curvilinear. In a ship with a curvilinear stern, the ports may be disposed so as to allow guns to fire in any direction diverging from a centre within the ship; and at the same time the after broadside guns may be trained so as to fire obliquely towards the fore or after part of the ship. Thus there will be afforded several intervals opposite the stern and quarters, within which the lines of fire may cross each other; and consequently the defence will be as powerful about the stern as at any other part of the ship. It may be added that when the guns in a square stern are trained at their greatest degree of obliquity to the sides of the ships, their muzzles will be considerably within the timbers; and consequently, in firing, some danger may exist of blowing away part of the stern or quarter. The curvilinear form is now, with slight modifications, generally adopted for ships of war; and the only objection hitherto made to it is that the interior accommodations are thereby rather diminished.

In 1791 there was formed, in London, a Society for the Improvement of Naval Architecture; and its first steps consisted in offering prizes for the best papers which should be written on the subject of the resistance of fluids, on designs for vessels, on the proportions of masts, &c. The association threw much light on the art of constructing ships; and both the theory and practice of that art have been advanced by means of the school which was attached to the Naval College at Portsmouth, under the superintendence of Dr. Inman. During the year 1860, however, an Institute of Naval Architects, under the presidency of Sir John Pakington, was originated in London, and bids fair to bring together the ablest members of the profession in England, as also men eminent in mechanical science. The late principal of the School of Naval Architecture, the Rev. Dr. Woolley, has already given a useful paper on mathematical theory, while men like Maudslay, Scott Russell, Grantham, Fairbairn, &c. have contributed valuable assistance. ('Transactions of the Institute of Naval Architects for 1860.')

In the present article it is intended to give some account of the mathematical principles of naval architecture; the mechanical construction of ships being reserved for the articles SHIP-BUILDING and STEAM VESSEL.

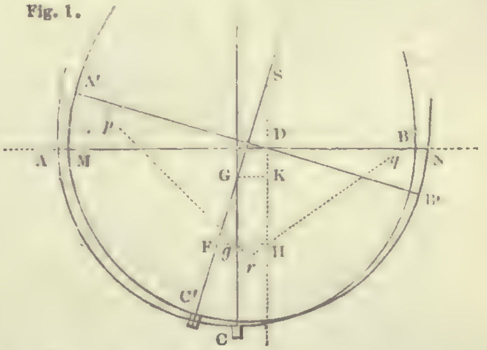
The body of a ship about its middle has nearly the form of a portion of a hollow cylinder, with its axis horizontal, and its convex surface downwards. Above the surface of the water on which it floats the sides are curved, so as at the head to have, in a horizontal direction, the form of a Gothic arch more or less acute. The breadth diminishes gradually towards the stern, which above water is either a plane surface nearly perpendicular to the ship's length, or, agreeably to the construction introduced by Sir Robert Seppings, curved so as to have, in a horizontal section, nearly the form of a semi-ellipse. Below the surface of the water the body of the ship is curved in a horizontal direction towards the head and stern, so as to terminate at those places in angles which diminish from that surface downwards; and thus a vertical section, taken perpendicularly to the length of the ship, at some distance from the middle towards either extremity, presents on each side the form of a curve of contrary flexure.

Experiments have shown, that when the quantity of sail is the same, the velocity of a ship is increased by increasing the ratio between its length and breadth, and both English and French constructors have gone on for many years augmenting that ratio; but this increase has its limit. The advantage of diminished breadth is accompanied by a diminution of stability, and a deficiency in this respect may produce serious evils. It may prevent the use of the lower guns on the lee-side from the fear that the ports may be under water, and the use of the guns on the weather-side from inability to give them sufficient depression; and by causing the keel to take an oblique position in the direction of its depth, the lateral resistance of the water being diminished, the lee-way of the ship is increased. The power of the rudder and sails to produce rotation about a vertical axis is greater in a long than in a short ship, because the rudder and sails are at greater distances from that axis, and because the impulse of the water on the rudder is more direct: yet the resistance which the water opposes to that rotation increases in a still higher ratio; and thus the difficulty of working to windward is increased with the length of the ship. Lastly, the quantity of artillery in a ship will indirectly affect the relation between the length and breadth; for an increase of weight above water produces a diminution of stability by causing the centre of gravity of the ship to be more elevated, and this evil must be counteracted by increasing the breadth. In several English ships of war carrying from 46 to 120 guns, it has been found by admeasurement that the ratio of the breadth to the length varied from $\frac{1}{3{\cdot}93}$ to $\frac{1}{3{\cdot}61}$, and that it had no dependence either upon the number of guns or upon the tonnage of the ship. The greatest length which may be given to ships of war is a point still undetermined; and the length seems to have hitherto gone on increasing in the navies of all nations. In 1786 was built the Victory, of 100 guns; this was then the greatest three-decker in the British service, and its length was 186 feet. In 1793 the Ville de Paris, of 110 guns, and 190 feet long, was built at Chatham; and in 1809 was built the Caledonia, of 120 guns, whose length was 205 feet, while the Hood of 91 guns and 3232 tons, launched, at Chatham, in 1859, is 238 feet long, and the Galatea frigate, launched in 1859, having 26 guns, and being of the burden of 3202 tons, has a length of 280 feet.

In the Vernon, and other ships which were built according to the designs of the late Sir William Symonds, the form of a transverse section passing vertically through the hull differs from that which had been before given to ships, in exhibiting an increase of breadth above the plane of floatation (a horizontal plane passing through the ship when she floats upright, and coinciding with the surface of the water). This construction produces, without any diminution of velocity, an increase of stability not only when the ship is afloat, but also when, on lying aground, she is subject to the force of waves against her side. It may however be said to be attended by the disadvantages of too great stability; that is, it may cause the ship to be considerably strained, and the masts to be carried away by a sudden impulse of the wind.

The lateral action of the wind against the sails, and of the waves of the sea against the hull of a ship, are the causes that the plane passing through its masts is made to decline from the vertical position which it has when the ship is at rest; and the ship is then prevented from being overturned only by the reaction of the water against the bottom and sides. The momentum of this reaction is that which is called the stability of the ship. The axis of the rotation has been placed by different writers in different situations, but both Bouguer and Euler have proved that, if the ship has not at the same time a pitching motion, it should be considered as a horizontal line passing through the centre of gravity of the ship. In order to find approximatively the dependence of a ship's stability on its length and breadth, let it be supposed that the ship is a homogeneous solid in the form of a prism or segment of a cylinder having its axis in a horizontal position; and, the vessel being supposed to float upright, let A B C (*fig.* 1) be a transverse section through the immersed part in a vertical plane passing through G and g, which are respectively the centres of gravity of the whole solid and of that part (A B) coinciding with the surface of the water: let also A′ B′ C′ be the position of the same section when the vessel is inclined. Now, while the weight of the ship remains the same, the volume of the immersed part is the same whether the ship be upright or inclined, and the volume raised above the water by the inclination on one side is equal to the volume depressed below it on the other; therefore the area M C′ N may be considered as equal to A C B, and A′ D M to B′ D N. Next let p and q be the centres of gravity of the trilateral spaces last mentioned; then, by mechanics, the centre of gravity of M D B′ C′ will be at some point, as r in $p\,g$ produced, the displacement of g by the inclination being supposed to be very small; and the centre of gravity of M C′ N (the section immersed when the solid is inclined) will be at some point H in $q\,r$: also—

Fig. 1.



$$\mathrm{A'B'C'} : \mathrm{A'DM} : : pr : gr, \text{ and}$$

$$\mathrm{MC'N}\ (=\mathrm{A'B'C'}) : \mathrm{B'DN}\ (=\mathrm{A'DM}) : : gr : r\mathrm{H}.$$

Therefore, $p\,r$ and $q\,r$ are cut proportionally in g and H; and g H is parallel to $p\,q$. Consequently—

$$pr : gr : : pq : g\mathrm{H},$$

$$\text{or } \mathrm{ABC} : \mathrm{A'DM} : : pq : g\mathrm{H};$$

and if the inclination of the ship is very small, g H may be considered as parallel to A B. Draw the vertical line H S, and G K parallel to A B; then $g\mathrm{H} = \mathrm{GK}$.

The area A B C may represent the volume (V) of the displacement, or of the immersed part of the ship; and the area A′ D M, the volume raised above or depressed below A D in consequence of the inclination. This trilinear space being supposed to be very small, it may be considered as a triangle right-angled at M: and if the length and half-breadth of the solid be represented by l and b respectively, we have $\frac{1}{2}\mathrm{A'M}.l.b$ for the representation of the elevated or depressed volume. But A′M varies with b; therefore, such volume varies with $l.b^2$. Again, by mechanics, the distance of the centre of gravity of each of those volumes from a horizontal line passing through D, in a direction parallel to the axis of the solid, is equal to $\frac{2}{3}b$; therefore, the line $pq = \frac{4}{3}b$, or pq varies with b. Then substituting, in the last proportion above, V for A B C, $l.b^2$ for A′DM, and b for pq; also putting G K for g H, we find that G K varies with $\frac{l.b^3}{\mathrm{V}}$; or $\mathrm{V.GK} \propto l.b^3$. Now the force of the water to prevent the ship from being overturned taking place, by hydrostatics, in the vertical line H S passing through H, and being represented by V; also the ship being supposed to turn about a longitudinal axis passing through G, we have V.G K for the momentum of the ship's stability; but the triangle GKS is similar to A'MD, all the sides of one being perpendicular to those of the other: therefore

A'M : DM : : GK : GS.

Again, A'M varies with DM; therefore, GK varies with GS and V.GS ∝ $l.b^3$: that is V.GS expresses also the momentum of the ship's stability. The point S is called the meta-centre, and it indicates the most elevated position which the centre of gravity G can have consistently with the stability; for when G coincides with S, it is evident that the above expression vanishes.

Since the depth of the ship does not enter into the expression $l.b^3$, it may be inferred that when ships have equal lengths and breadths, they will have equal stabilities, whatever be their depths. Again, when they have equal breadths, their stabilities will vary with their lengths; and when they have equal lengths, the stabilities vary with the cubes of their breadths. It follows also that, in general, the stability of a ship is directly proportional to its length and to the cube of its breadth, whatever be its depth.

In the next place, in order to find approximatively the relations between the velocity of a ship and its dimensions, let the ship be represented by an isosceles triangular prism having the greatest rectangular surface uppermost and parallel to the surface of the water, and the triangular ends perpendicular to that surface, so that the fore and after parts are rectangular planes inclined to the same surface; then for the present purpose we may assume that the resistance experienced in moving through the water is expressed by $v.^2 \text{A} \sin^3 \text{I}$. [HYDRODYNAMICS], where v is the velocity of the vessel, A the superficies of the inclined front, and I its inclination to the surface of the water. But the resistance of the water is directly proportional to the moving power, that is, to the pressure of the wind on the sails, and this last varies with the area of the sails, which may be represented by a: therefore, $v^2 \propto \frac{a}{\text{A}.\sin.^3 \text{I}}$. Again, the momentum of the ship's stability is directly proportional to the momentum of the wind on the sails, and the latter is expressed by the product of the area of the sails into the height of the centre of pressure (centre of gravity of the sails) above the axis of rotation: now this height varies with the height of the sails; that is, with the square root of their area, the sails in different ships being supposed to be similar plane figures. Therefore, the momentum of stability varies with $a^{\frac{3}{2}}$, or $a \propto$ (moment. of stability)$^{\frac{2}{3}}$. Let l be the half length of the vessel, b its breadth, and d its depth; then the momentum of stability as above may be represented by $l.b^3$, A will be equal to $b(l^2+d^2)^{\frac{1}{2}}$ and $\sin^3 \text{I}$ to $\frac{d^3}{(l^2+d^2)^{\frac{3}{2}}}$. Hence, $v^2 \propto \frac{l.^{\frac{2}{3}} b(l^2+d^2)}{d^3}$; and this being simplified, neglecting $l^{\frac{2}{3}}$, which may be considered as small when compared with $l^{\frac{8}{3}}$, we have $v \propto \frac{b^{\frac{1}{2}} l^{\frac{4}{3}}}{d^{\frac{3}{2}}}$.

This expression indicates that the velocity will be increased by diminishing d, which may represent the ship's draught, or the depth to which she is immersed. It is evident also that the like effect will take place if the length or the breadth, or both, are increased (the breadth of the sail being supposed to increase with that of the ship); and since, in this case, the stability will at the same time be increased, this will permit the ship to carry a greater quantity of sail; but the number of the crew being supposed to vary with the area of the sail, an increase of the latter is in general attended with a corresponding increase of expense. The factors in the value of v being different powers of b, l, and d, it thence follows that ships having the same proportions possess unequal sailing properties; it may be perceived indeed that a small ship built according to the proportions of a large one which is known to sail well will not possess the like good quality. On the other hand it may be inferred that a vessel having the same proportions as a good one of smaller dimensions will be superior to the latter. If two ships carry sails proportional to their stabilities, and if the height of the lower tier of guns above water be the same in both when the ships float upright; then, the inclinations of the planes of their masts being also supposed to be equal, the lower guns of the smaller ship will be farther from the water than those of the larger ship, and, in action, the latter might be in danger when the other would be safe. Consequently, if the greatest possible quantity of sail be given to the smaller ship, a smaller quantity relatively to its stability ought to be given to the larger.

The discovery of the elements on which depend the stability and the sailing properties of ships will probably be made rather by studying the proportions of such as from experience have been found to possess the desired qualities, than by purely scientific researches; and as a step preparatory to this study it will be necessary to be acquainted with the methods by which, in a body like a ship, which cannot be considered as corresponding to any geometrical solid, the areas of sections, the volume of the whole or of the part immersed in the water, the position of the centre of gravity of the hull or the sails, &c., are found.

The method of equidistant ordinates is generally used for these purposes; and in finding the area of a section, some line in it being taken as an axis, an uneven number of lines as ordinates are drawn or supposed to be drawn at equal distances from one another perpendicularly to that line till they meet the surface of the ship. The lengths of these ordinates being known by actual admeasurement, or by the scale of the drawing, and also the distance between them; and the curve line in which the plane of the section meets the surface of the ship being considered, between every three consecutive ordinates, as an arc of the common parabola; by Sterling's rules, the area will be found as follows: let the figure represent the half plan, divide it into any number of equal parts, say eight.

Fig. 2.

Then area $= \frac{r}{3}(\text{A}+4\text{P}+2\text{Q}) = \frac{2r}{3}\left(\frac{\text{A}}{2}+2\text{P}+\text{Q}\right)$ in which

A = sum of first and last ordinates,
P = sum of even ordinates,
Q = sum of remaining ordinates,
r = common distance between the ordinates;

or, according to his second rule, the ordinates may be drawn so that the equal intervals are made some multiple of the number 3, in which case the

$$\text{Area} = \frac{3r}{8}(\text{A}+2\text{P}+3\text{Q}) = \frac{3r}{4}\left(\frac{\text{A}}{2}+\text{P}+1\tfrac{1}{2}\text{Q}\right) \text{ where}$$

A = sum of first and last ordinates,
P = sum of 4th, 7th, 10th, &c., ordinates,
Q = sum of remaining ordinates,
r = common distance.

Either rule may be used, for whether the curve be considered as a common parabola, or as a cubic parabola, will scarcely affect the practical result.

By either of these rules the area of a vertical section through the middle of the ship's breadth in a longitudinal direction, or through any part of the ship's length in a transverse direction, and also the area of a horizontal section coincident with or parallel to the surface of the water, may be found. The same formulæ may be applied to determine the volume of the whole hull, or of the displacement; for this purpose vertical sections may be supposed to pass through the equidistant ordinates drawn perpendicularly to the longitudinal axis of the ship, and their areas to be computed as above. The formulæ may also be employed to determine the momentum of any part of the ship with respect to some line about which it may be made to turn, or with respect to a plane passing through such line.

In order to find the centre of gravity of the displacement, that is, of the immersed part of the ship (considered as a homogeneous solid) when the ship floats upright; imagine that immersed part to be divided by equidistant vertical planes perpendicular to the ship's length, and also by equidistant horizontal planes; then the area of each horizontal section between every two vertical planes being multiplied by the vertical distance of that horizontal section below the surface of the water, and all the products being added together by either of the above formulæ, the sum will be the momentum of the immersed part with respect to the horizontal plane at the surface of the water. This momentum being divided by the volume of the immersed part computed as above, gives by mechanics the distance of the centre of gravity below the surface of the water. In a similar manner may be found the position of the centre of gravity with respect to a vertical plane passing perpendicularly to the length of the ship, suppose at one of its extremities; and thus its position may be completely determined. From the symmetry of the ship's figure on each side of a plane passing through its masts and keel, the centre of gravity of the whole ship will always be in that plane; and that of the immersed part will be in the same plane when the ship floats upright.

The position of a vertical line passing through the centre of gravity of the whole ship may be found by determining that of a vertical line passing through the centre of gravity of the displacement; for, by hydrostatics, when the ship floats with its masts upright, these lines are coincident. But the determination of the place of the centre of gravity in this line is a problem of considerable difficulty on account of the complexity of the subject, arising from the form of the hull, the positions of the masts, rigging, guns, lading, &c.: and it can only be found mathematically by ascertaining the place of the centre of gravity and the weight of every separate object constituting the mass of the ship and its lading. The momenta of all these objects being computed with respect to any one plane, as that of floatation (the horizontal plane at the level of the water), the difference between the sums of the momenta of the objects above and below that plane is, by the nature of the centre of gravity, equal to the product of the weight of the whole ship into the distance of the required centre of gravity from the same plane. Hence the situation of this point might be found.

The most simple mechanical method of finding the centre of gravity of a ship is probably that which was proposed by Mr. Major in the 'Annals of Philosophy,' June, 1826. It consists in making the ship when afloat heel (the plane of its masts to incline) through equal angles by means of weights applied successively to a mast, and made to act horizontally at different distances above the deck; these weights being reduced to directions perpendicular to the inclining mast (by multiplying them into the cosine of the inclination), and then multiplied into their respective distances from the unknown centre of gravity of the ship, will give two products which are equal to one another; each of them being equal to the momentum of the resistance by which the water tends to prevent heeling; hence by algebra the distance of the centre of gravity from either of the points at which the weights are applied may be found.

In the expression for the momentum arising from the pressure of the wind against the sails, it is usual to consider the whole force of the wind as acting at the centre of gravity of the sails; and this point may be found by multiplying separately the area of each sail into the distance of its centre of gravity above a horizontal axis passing through the centre of gravity of the ship. The quotient arising from the sum of these momenta divided by the sum of the areas of all the sails will give the distance of the required centre of gravity above that axis; and similarly the position of the centre of gravity of the sails with respect to any vertical line as an axis may be obtained.

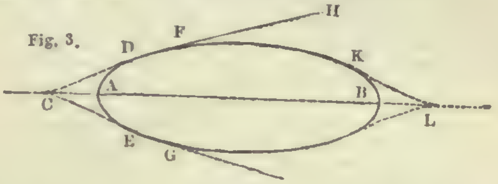
To find the centre of gravity of the displacement, or of the immersed part of the ship supposed to be homogeneous, when the plane of a ship's masts is made to incline by the lateral action of the wind, the axis of rotation being supposed to be a horizontal line passing through the centre of gravity of the whole ship, there must be first obtained by trial the position of a horizontal line in which the plane of the surface of the water will cut the body of the ship when in the upright and inclined positions respectively, so that the volume of the part raised above the water in consequence of the inclination may be equal to that of the part depressed. Let a line passing through D, *fig.* 1, perpendicularly to the paper, be that horizontal line; then the sum of the momenta of the elevated and depressed volumes may be found by computing the areas of the trilineal figures A′DM, B′DN, in all the vertical sections taken at equal distances from one another in the direction of the ship's length, multiplying them separately by the distances of their centres of gravity from a vertical plane passing through the same horizontal line, and then adding all the products together by one of the formulæ above given. In the 'Quarterly Journal of Science,' April, 1830, the area of either triangle, as A′DM, is expressed by $\frac{\gamma+\gamma''}{2}\gamma' \sin\frac{1}{2}\theta$, where $\gamma =$ DM, $\gamma'' =$ DA′, $\gamma' =$ a line drawn from D to A′M, bisecting the angle A′DM, or θ (the angle of heeling). Also the momentum of the same triangle with respect to the point D is expressed approximatively, and supposing the angle of heeling to be 7° (the greatest at which a ship of war can use her windward guns), by $.0203\gamma\gamma''(\gamma+\gamma'')$.

In order to find an expression for the stability of a ship, let G be its centre of gravity, and when the ship floats upright let g be the centre of gravity of the immersed part supposed to be homogeneous. Now when the plane of the masts is inclined, g will be situated at F, and in that case let H be the place of the centre of gravity last mentioned; then by mechanics, FH will be equal to the quotient arising from the division of the sum of the momenta of the elevated and depressed volumes by the volume of the immersed part of the ship. But if θ be the angle of inclination, we shall have Fg = GF sin θ; therefore gH or GK may be found. This being multiplied by the weight of the ship and its burden (= the force of the reaction of the water in the direction HS), gives the expression for the stability.

The plane of a ship's masts is made to decline from a vertical position not only by the action of the wind against the sails when the direction of the wind does not coincide with that plane, but also by a wave striking the ship in a direction oblique to the horizon and to the plane of the masts; and in both cases the variations in the force by which the inclination is produced and the re-action by which the water tends to bring back the plane of the masts to a vertical position cause the ship to roll about some longitudinal axis, which is supposed to pass horizontally through the centre of gravity of the whole ship. Now, if a horizontal plane coincident with the plane of floatation pass through AB when the ship floats upright, and G, the centre of gravity of the ship, be below that plane, as in *fig.* 1; in order to preserve the equality of the immersed volume when the ship is inclined, the plane which passed through AB must take such a position as A′B′. This will cause G to ascend; that is, the ship will rise on the water. On the other hand, if G had been above AB when the ship was upright, the latter would descend on the water when it is made to take an inclined position. Such rising or descending is a cause of the ship being shook or strained in rolling; and this evil can be avoided only by having the centre of gravity, G, coincident with the plane of floatation. It is necessary to observe, on the other hand, that by keeping that centre higher, or bringing it nearer to the meta-centre S, the stability of the ship, which varies directly with the distance GS or GK, is proportionally diminished. The pitching of a ship, that is, the alternate elevation or depression of either extremity of the ship as the latter passes over a wave, is attended by a corresponding rising or descending of the whole ship; and the strain thus produced will evidently be so much the less as the centre of gravity is nearer the level of the plane of floatation and the middle of the ship's length. It should be stated here that, since a ship in tacking is supposed to turn horizontally about a vertical axis passing through its centre of gravity, the resistance then experienced, which is proportional to the square of the distances of its extremities from that axis, will be a minimum when the centre of gravity is in the middle of the ship's length; but, on the other hand, the power of the rudder depending on its distance from the same axis of rotation, that power would be increased by having the centre of gravity at some distance before the middle point.

When a vessel which is partly immersed in a fluid moves through that fluid, it always experiences a resistance in a direction contrary to that of its motion, in consequence of the inertia of the water; but it experiences also a resistance on account of the particles of water which are immediately struck by the vessel, and those immediately beyond them to a certain distance, being for a time compressed on all sides by the vessel and the surrounding fluid, and thus compelled to rise above the general level. The elevated fluid will be highest before the middle point at the bows of the vessel; and the hydrostatical pressure arising from the elevation, combined with the reaction of the neighbouring fluid, will cause the particles to flow off laterally in the direction of some curve-line whose convexity is towards the vessel, after which they will mix with the fluid on each side. Now let ADB, *fig.* 3, be a horizontal section through the ship at the general level of the water, and let CED be the space occupied by the confined water in front of the ship; then if an artificial prow of that acute form were given to the ship, the particles of water contiguous to the sides of such prow would create very little resistance in addition to that which arises from the inertia of the water, while the latter resistance will evidently be so much the greater as the bows are more obtuse. Beyond D and E the particles flowing along the side exert forces arising from friction, adhesion, and the lateral pressure of the neighbouring water; and at certain points, as F and G, they pass off in the directions of tangents at those points. The force of friction and adhesion is very considerable, particularly if the surface is rough and unequal; and if the vessel is moving with or against a current, the pressure against its sides is equal to that which would be experienced if the water were at rest, diminished or increased on any given area by the weight of a column of the fluid whose base is that area, and whose height is that which is due to the velocity of the water. It has been found moreover by experiment, that if both vessel and fluid are in motion, with equal velocities in the same direction, the buoyancy of the vessel is the same as if both were at rest; but when the velocity of the vessel is less or greater than that of the fluid in the same direction, the vessel either sinks or rises in the fluid by a quantity equal to the height due to the difference of the velocities, and this circumstance must in some measure modify the resistance of the water against the vessel.

Fig. 3.



Besides the resistance arising from the friction of the water along the sides of the vessel, there must be noticed the diminution of pressure against the after part, in consequence of the water displaced by the motion not falling in behind with sufficient velocity to bring the surface there to the same level as in front. The particles of water diverging from the sides of the vessel in oblique directions, as FH, are by the lateral resistance of the neighbouring fluid deflected so as to describe curve-lines which finally unite behind the stern in some point, as L. But the force exerted to deflect the particles from the direction FH causes a diminution of the pressure which the water would have otherwise exerted against the after part of the vessel; and consequently it is to be considered as an additional power opposing the forward movement of the vessel. The force of deflection, and consequently the retardation, will evidently be less in proportion as the tangent FH is nearer to the side of the vessel, or as the point F is more distant from the stern; and this circumstance indicates the advantage which ships of considerable length have over others. It is easy to understand however from the breaking and foaming of the water at the head and stern of a vessel when moving with considerable velocity, that the effects of the resistances will be greatly modified by the collisions of the particles of water with each other, and with the surface of the vessel, in consequence of the shocks produced by its motion, and by the effort of the water to return to a state of equilibrium.

In order to obtain an expression for the resistance of the water against a ship, the part of the immersed surface which is before the greatest transverse vertical section is supposed to be divided by a number of such transverse sections at equal distances from one another, measured perpendicularly between them, and by a number of sections parallel to the plane of floatation at equal distances from one another vertically. Thus the surface of the immersed part in front of the greatest transverse section is divided into trapezoidal figures; and a like division of the immersed part of the ship's surface abaft of the greatest transverse section is made. Each trapezoid, in an orthogonal projection of the fore and after part of the ship made on a plane parallel to the greatest transverse section, is then divided into two triangles by a diagonal line, and the area of each projected triangle (found by admeasurement of its sides on the scale of the drawing) is multiplied into the resolved force of the water upon it; that resolved force being expressed by the absolute force multiplied into the square of the sine of the inclination of the triangle on the ship's surface to the direction of the motion. The sum of the products is taken for the whole resistance of the water against the ship. In comparing the resistance against one ship with the resistance against another, it is evident that the absolute force of the water on each may be represented by unity.

Experiments sufficiently prove that the resistance experienced by a body in moving through a fluid is less when the greatest breadth of the body is at some distance before the middle of its length, than when it is precisely at that place, but the most advantageous situation of what is called the *midship section* (the greatest vertical section taken perpendicularly to the length of the ship) is far from having been as yet determined. In order to find its dependence upon the direct resistance of the water, M. Chapman proceeds in the following manner: He considers the ship to be represented by a solid in the form of two isosceles wedges joined together at their heads and to move in the water with the planes which are perpendicular to their edges parallel to its surface. Now it is evident that when the solid is at rest in still water, the opposite pressures of the water against the faces in front, and against those which are behind the plane of junction, or of the greatest transverse section, will be equal to one another in directions parallel to the length of the solid. Also that, when in motion, the front faces will experience directly that resistance of the water which is due to the velocity of the solid, and that the after faces, by receding from the water in consequence of the advance of the body, will lose a portion of the pressure which they would have experienced had the body been at rest, and which would thus have indirectly contributed to force the body forward. It must moreover be observed that the water is driven forward in front of the vessel with a velocity which may be represented by v'; and that as the water in front becomes higher than that which is behind the greatest transverse section, it will flow towards the stern with a velocity which may be represented by v''. Hence if A be the sum of the areas of the two oblique surfaces in front of that greatest section, and B that of the surfaces abaft of the same section; also if θ and θ' be the inclinations of those surfaces respectively to the line of motion, and v be the velocity of the body, we shall have, supposing the resistance to vary with the square of the velocity and the cube of the sine of the inclination,

$$\mathrm{A}\,(v-v')^2 \sin.^3\theta + \mathrm{B}\,(v+v'')^2 \sin.^3\theta'$$

for the value of the whole resistance; or, for A sin. θ and B sin. θ' putting their equal C (the area of the transverse section) the expression for the resistance becomes

$$\mathrm{C}\left\{(v-v')^2 \sin.^2\theta + (v+v'')^2 \sin.^3\theta'\right\}.$$

This formula indicates that such a body will always meet with less resistance when C is in front, than when it is abaft of the middle point in the length; that is, when θ is greater than θ': it indicates also that the place of the greatest breadth when the resistance is a minimum depends on the values of $v-v'$ and of $v+v''$, and that the greater v' and v'' are with respect to v, the farther should the greatest breadth be in front of the middle point.

Imagining a horizontal section through a ship at the surface of the water to present the form of four portions of parabolas, the two in front of the greatest transverse section being similar and equal on opposite sides of the longitudinal axis; and likewise the two portions abaft of that section being similar and equal to one another, but different from the two former portions, Chapman finds, as approximations to the place of that greatest section, that its distance in front of the middle of the ship's length may be four, six, or eight times the horizontal distance of the centre of gravity of the whole ship from that middle point. And his observation is that the first distance might serve for sharp vessels, as frigates, and the last for merchant ships, which are much broader than the others in proportion to their lengths. Colonel Beaufoy's experiments with solids of various forms indicate that, in general, the distance of the midship section in front of the middle point in the length should be one-tenth of the length.

It must be understood that the assumptions on which the formulæ expressing the relations between the principal dimensions of ships, and between the dimensions and velocity, have been investigated, are far from being conformable to the circumstances of a ship when moving through the water, and the same may be said of the above process for finding the place of the greatest transverse section; consequently, the formulæ afford but remote approximations to the rules which should guide the naval architect in the formation of a design. A far more perfect knowledge than we have at present of the action of the wind on the sails, of the resistance of the water, and of the conditions of stability in a ship, will be necessary before the results of analysis will be capable of being applied directly to the details of construction.

Having thus noticed the general mathematics involved in the question of producing the best form of floating body for propulsion along the surface of a fluid, and as adapted to the conveyance therein of heavy weights from place to place; the forms under which such bodies are usually constructed, either for purposes of war or commerce, demand our notice. The consideration of the mode of construction forms no part of the requisites of this article; we refer, therefore, to the general question of naval architecture, as illustrated under the words SHIPBUILDING and STEAM-VESSEL.

The most essential conditions in the construction of a ship are, that it be capable of carrying its stores and its artillery or lading; that it be moved by wind or steam with great velocity, and that it readily obey the motion of the rudder; that it have the necessary stability, so as not to be overturned when acted upon by the wind or waves; and, finally, that its rolling or pitching be attended with as little strain as possible on the timbers. These conditions are in some respects contrary to each other; and the degree of attainment for each will depend in part on the purpose, whether of war or commerce, for which the ship is built. The skill of the architect lies therefore in adopting such a construction as shall allow the quality most required to be obtained in the highest degree, without being attended by too great a sacrifice of the others. The form indicated above has by experience been found to afford the means of uniting the different conditions, as far as they are consistent with each other; but that form is capable of being varied within very distant limits. The subject of the resistance of fluids against bodies immersed in them is also so imperfectly known, that the most proper proportions which the several dimensions should have to each other, in order that such resistance may be as little as possible, are yet to be determined; and in the present state of science, those proportions can only be obtained from the dimensions of ships of different classes which have been observed to possess the best sailing properties.

In merchant ships an ample capacity is frequently of more importance than a great velocity in sailing; and in this case the relations between the length, breadth, and depth depend less upon hydrodynamical principles than the corresponding relations in ships of war. With respect to the latter, it is observed by Mr. Morgan, in his papers on naval architecture, that the number and weight of the guns constitute the basis of the design; for from these the weight of the whole ship, or the volume of the water which it will displace, may be estimated. The distance between the guns on the decks must be such as by experience has been found sufficient for working them; and hence the number of decks being given, the least length which the ship should have becomes known. The breadth also must in part be determined by the artillery; for on each side of the ship, between the hatches or ladder-ways and the rear of the gun-carriages after the recoil, there must be room for a free passage; but this element must also be great enough to afford the necessary stability, that the tendency of a lateral wind to turn the ship about a longitudinal axis may be resisted. The draught of water (the depth to which the ship is immersed) may depend on the depth of water in the harbours and roadsteads; but it should also be determined from experience, so that the ship may be prevented as much as possible from making leeway; and the height of the ship above water must be such that, while the upper tiers of guns are kept as low as possible, the height of the lowest tier above the water, when the ship floats upright, may be not less than six feet, in order that the lower guns may be worked when the ship has considerable inclination. Finally, the form of the body must be that which is most favourable for velocity, by causing the least possible resistance of the water at the bows and along the sides; which allows the greatest lateral resistance; and which will permit the rudder to act with most effect in causing the ship to be turned about a vertical axis. And if, when in the design for a ship all these conditions are fulfilled, the displacement (weight of the volume of water which would fill the space occupied by the ship below the general surface of the water in which she floats) is equal to the whole weight of the ship, the several dimensions may be considered as nearly correct.

With regard to ships of war, a reference to our word NAVY will show that so great are the changes resulting from the adoption of the screw as a means of auxiliary propulsion, that, together with a total revolution commenced in the system of armament, the discussion herein of embryo theories would be incompatible with our plan. Under the words GUN-BOAT, CLIPPER, &c., the subject has been already touched upon, but a few general remarks will be added under the heading STEAM-VESSEL.

Ships intended for the merchant service may be divided into three classes, as either "passenger carrying," "cargo vessels," or "passenger and cargo vessels." Among the first may be found perhaps some of the most beautiful models of steamers which the art of man, at this period, can produce. It is necessary, however, to concede that notions of beauty in a ship vary as our notions of their adaptation to certain purposes; for if we take speed alone as our standard of reference, slimness of form and lightness of rig appeal to the judgment, while the nautical connoisseur will, like the jockey among horses, detect at once among shipping the distinctive qualifications which stamp the racer, the charger, or, so to speak, the horse of burden.

Unfortunately, however, this *apparent* facility of rough appreciation forms one of the drawbacks to which naval architecture is liable. It is nevertheless capable of demonstration, that as in the horse an expectation of speed or otherwise is inferred by closer inspection, say of the length and freedom of the femur, so may the nautical eye scrutinise profitably various of the undermentioned qualifications of the ship. That a ship whose hull has been constructed according to the best rules of art does not always fulfil the conditions required, may depend on several causes. If the burden is placed too low, the rolling will be heavy, and the masts may be endangered; on the other hand, if the burden is too high, there may not be sufficient stability. With all the researches which have so lately been renewed, there seem to remain a few well recognised and established laws as to form which cannot be dispensed with in the construction of a perfect ship. It is by means of these that the unscientific builders of the country sometimes produce wonderfully good models. The following are the principal, namely :—

The bow should be sufficiently sharp to cleave the water with the least possible resistance :

Of sufficient fulness above load-water line to prevent too great plunging in bad weather :

Sufficiently free from unnecessary top-weight also to ease a ship in a sea way :

A bow in which the floor extends as far as possible into the forefoot, but blends easily into the general lines of the hull; serving as another check on inconvenient vertical motion.

The hull should have bearings or powers of floatation, so distributed as to sustain the internal weight without strain upon any particular part of the general frame of the vessel :

Should be so capacious as to admit of ample stowage, while its displacement at any depth presents a water-line free from too great curvature.

The floor should have such an arrangement of draft lines as to admit of both speed and stability, according to the work to be done by the vessel; for speed is well known to be influenced greatly by the fulness or otherwise of the midship section *at the bilge*, inasmuch as the shape of this part contributes largely towards the delivery or retardation of displaced water as it passes into the *run* of the ship past the stern-post : great proportionate length in a ship permits a fuller bilge line.

The stern should have the submerged part (called the *run*) as nearly wedge-shaped as possible in its water-lines, as viewed from above : the smaller the angle of the wedge the *cleaner* the run is said to be :

The lines of the run to spring from or blend with the lines of the hull without sudden change in the curve :

While so clean as to cause no dead water, yet to have the bearings above the light-water line so judiciously adjusted in the vertical sections as, from the capacity and gradual displacement of water at such times, to furnish an easy check to the violent motion of rolling or pitching :

So well arranged in its upperworks as to prevent unnecessary top-weight, while giving sufficient internal space for cabins and the requisite deck operations :

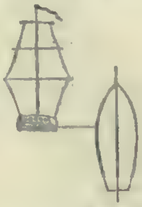
A proportion of length and breadth so nicely determined as not to give speed at the expense of stability, and *vice versâ* :

A forefoot so deep as to give what are called weatherly qualities, or to prevent the vessel, when close hauled, from being driven off the wind by every wave which meets the weather bow—while not so deep as to impede ready working in stays :

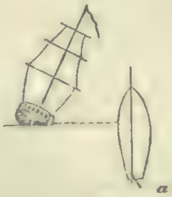
A heel so deep as to give sufficient power to the helm in its ample hold of the water, without increasing unnecessarily the draught of water.

It may well be imagined that the above requirements, so antagonistic in themselves, generate a vast variety of forms of vessels; but not even the absolute shape of the fabric itself can insure an accurate performance when under sail; for other important considerations arise even in the fitting and masting of the ship, as for instance :—

The masts should be so distributed in her length as to incline a little towards the stern (or should *rake*, as the phrase is); this has a double advantage: 1st, it tends to steadiness of the hull in a sea way, when moving upon her midship axis, in the action of pitching, inasmuch as the weight of the spars, sails, and rigging upon a raking mast has to be *raised* by the motion of the ship before the mast can be perpendicular; while in a perpendicular mast, such pitching motion is facilitated by any vertical disturbance of the water line, inasmuch as in this case the weight of the whole mast tends towards a lower point. 2nd, In a heavy gale the wind has less power on a raking mast when the ship is lying-to. And further, it has long been the practice to place the foremast of a line-of-battle ship very far forward, so far indeed as in some to plumb the forefoot. This has been supposed to be necessary from the general form of the hull, as a counteraction of too great an amount of weather helm when the ship heels, but it is scarcely questionable whether the new form of bow will not show the former disadvantage of placing the foremast, in some ships weighing perhaps thirty tons (including spars, sails, and gear), so far from the centre of gyration of the whole mass. It is no uncommon thing to see these old liners, when riding for instance at anchor in the Downs, pitching bows under, to the manifest danger of masts and everything. Another great defect of rig is mostly apparent in foreign vessels, wherein the lower masts are so long as to throw the centre of effort of their top-sails and top-gallant sails higher than necessary above the decks, and by thus increasing the leverage of the force of the wind, throwing the hull out of the perpendicular and distorting the water-line, as in the following diagram.



Water-line.



Water-line.

When such is the case, the vessel has a constant tendency to fly up to windward, and requires the helm to be so placed as to counteract this tendency, but it forms a complete drag upon her motion. (See *a* in the above figure.)

Enough has been said on the general consideration of a ship as a mere sailing body, as adapted to the propulsion of such bodies by steam. The subject will admit of further remark under the word STEAM-VESSEL. A few outline diagrams are here added in illustration of terms usually applied to the different descriptions of sailing vessels.

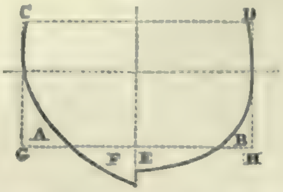
SHIPBUILDING, as a science, has, under the term Naval Architecture, become so extensive a subject as to render it difficult to condense within the limits of a concise statement, sufficient to illustrate even its main principles, without undue intrusion upon the consistent limits of a Cyclopædia.

The precise form of a ship need not here be a main consideration; under the word STEAM-VESSEL will be given such information hereupon as illustrates the question of speed; which, although belonging also to certain classes of sailing-vessels, is more immediately and more generally connected with steamers whose powers are dependent on a limited amount of their primary means of propulsion, namely, coal. We here only consider, under this word, the hull or body of a ship as a hollow shell, intended to accomplish a required displacement of water under different specific amounts of immersion. Were it merely the object to build such a fabric as is capable of floatation in a fluid at rest, the elucidation of principles already given would suffice; but we have to illustrate certain considerations which are conducive to *strength*: and a difficulty arises of fairly estimating the amount of strength demanded, not at any particular part in the frame of a ship, but throughout the whole mass; for it becomes a most intricate question to estimate in a ship even an approximate amount of *relative* strain, and its importance in the economical distribution of material may be said to comprise the most exacting demands on the skill of the accomplished mechanic and mathematician.

The subject here would evidently divide into two distinct branches; for while there exists in vessels of the mercantile marine a series of qualifications adapted to the general requirements of commerce, such as the carrying of heavy burdens, or of passengers, another class of ships is demanded of the naval architect which shall fulfil all the necessities of fighting ships; but those of the latter class will be more conveniently treated of under Steam-Vessel.

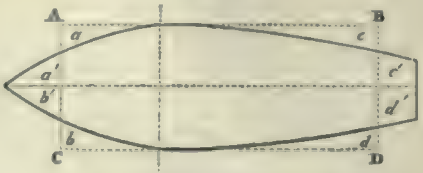
When a ship is to be constructed, the first consideration is the required amount of tonnage. This being once determined, a knowledge of the purpose for which the ship is intended regulates the builder in his fixing the amount of midship area, from which all the other dimensions originate. In forming the area of the midship section, the good qualities of the ship chiefly depend on the selection of the breadth (or beam as it is called) for on this rests the important question of stability or stiffness under sail. It is customary to consider the primary form of the ship as a quadrangular prism of contents equal to the required tonnage:—of course its midship section will be a rectangular parallelogram. Suppose, for example, it were required to build a ship of certain tonnage [Tonnage], whose midship sectional area is to be 805 square feet, and the beam 35 feet, then $\frac{805}{35} = 23$ feet the depth. The primary body plan and whole breadth plan would be as under:—

Fig. 1.



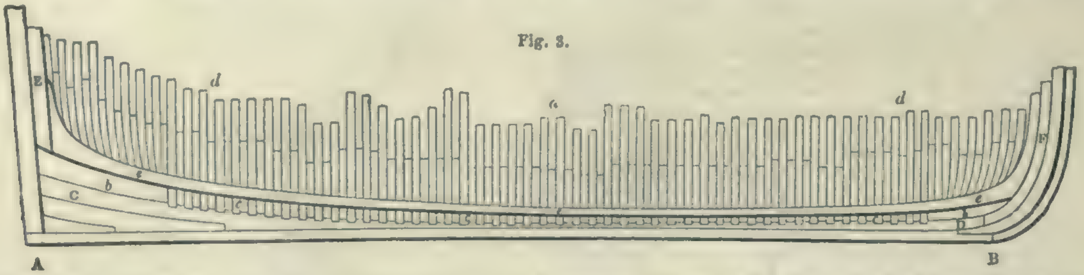
CGHD would be the midship area, CD the beam, CG the depth. Now although this represents the amount of displacement for tonnage, it requires the skill and taste of the naval architect to adapt the outline of such capacity to the requirements of the ship, having proper regard to speed, carrying qualifications, rolling, stability, &c. &c. This is to be done by an interchange of areas in the following manner:—Suppose a moderate amount of speed is to be blended with average carrying qualities, the dotted curve would be so drawn as to let the area E compensate for the abstracted area B; or if speed in particular be desirable, then the area F would compensate the area A. It will thus be manifest that a wide range of form is open to the shipbuilder, while his chief aim is not to disturb the amount of area of the midship section. And again taking the form of the ship at the load-water line—the primary parallelogram would be ABCD, a horizontal section of the primary quadrangular prism as under,—

Fig. 2.



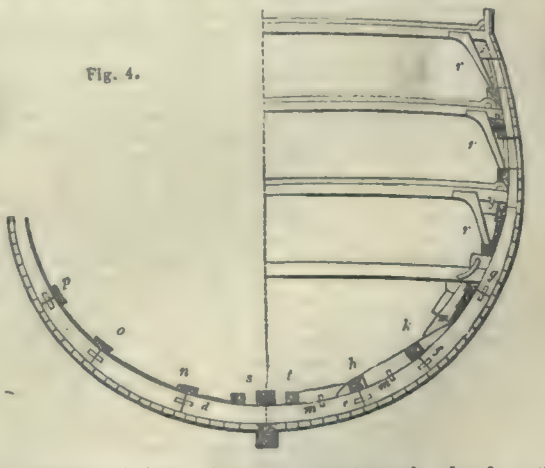
Now in order to shape the ends so as to give sailing qualities, it, as in the former case, again taxes the skill of the builder to interchange areas, so as not to disturb the gross displacement:—in the above figure we have supposed the area marked a to be taken from the parallelogram and transferred to a';—that marked c to be transferred to c':—b to b' and d to d'. Hence the outline in plan and section is determined, and drawings representing the necessary intermediate elevations and sections, generally on a scale of a quarter of an inch to a foot, are prepared, and copies of these, enlarged to the full size of the objects which they represent in the intended ship, are traced with chalk on the floor of an apartment called the "mould-loft." The length of the loft is generally equal to half that of the greatest ship which it may be proposed to build, and of the whole height of the hull in addition; so that there may be traced upon it a horizontal plan of half the ship in the direction of its length, and beyond one extremity of the plan a representation, in the same plane, of a transverse section of the ship in a vertical plane at the place of its greatest breadth. Such plan and section being laid down, there are drawn with chalk, from their proper places in the plan, representations of the timber ribs or frames as they would appear in as many transverse sections of the ship: pieces of plank about three-quarters of an inch thick are then cut so as to correspond to the forms of the timbers; and these, which are called the moulds, become the patterns by which the timbers are to be cut from the tree or log of wood. But, as such a mould can only give the form of the timber in the direction of its length, and as the oblique positions in which the timbers stand in the ship may cause the angle which the faces of each timber make with one another to be acute or obtuse, and to vary in the same piece, certain marks on the surfaces of the boards are used to indicate the directions in which the sides of the timbers are to be cut. The operation of cutting the timbers agreeably to the forms of the mould-boards is called "converting."

Fig. 3.



A row of blocks of oak are placed on the building-slip (ground cut in an inclined plane descending towards the water) in the direction of the length of the intended ship, so that their upper surfaces may be in a plane making an angle of about three degrees with the horizon; and on these blocks is laid the keel AB, *fig.* 3. This, which is the lowest timber of the ship, extends from one end to the other, and upon it is raised the whole fabric; it is of elm, and for a large ship it consists of two or more pieces scarfed together at their extremities. Timbers, called the "dead-wood," are then placed at C and D longitudinally upon the keel from each extremity of the latter towards its middle; the upper surface of this mass is cut in a curvilinear form *b*, *b*, and with this line the bottom of the ship's body is to coincide. At A and B, the extremities of the keel, the stern-post and stem-post are set up: the latter is curved near the bottom; and if the stern is to be what is called square, a particular frame, consisting of two transoms or horizontal timbers, and two side-pieces, is fixed above the stern-post, in order to determine the form which is to be given to this part of the ship. The sides and upper surface of the keel and dead-wood are cut to receive the floor-timbers (the lower portions, *d e*, *fig.* 4, of those timbers which are to form the ribs of the hull): these are placed across the keel perpendicularly to its length, and the other portions (called futtocks), *e f*, *f g*, &c., of which each rib is formed, are placed successively above them, abutting end to end, or the head of a lower one against the heel of that which is immediately above it. The ends of the futtock-pieces in every rib are made to fall near the middle of the length of those in the rib on each side of it; and they are united together by cylindrical coaks, or plugs of wood, which enter about two inches into those ends at the places of junction; *c*, *c*, *c*, &c., *fig.* 3, represent sections of the ribs made by a plane passing longitudinally through the middle of the keel, and the interior surfaces of parts of the ribs appear at *d*, *d*, &c. The ribs were formerly placed so that their planes were perpendicular to the keel, but Dr. Inman has disposed them so as to be in vertical positions when the ship floats upright. Except near the two extremities of the ship, their planes are perpendicular to a horizontal line drawn in the plane of floatation through the whole length; but at the bows always, and at the stern if the latter is to be curvilinear, the vertical planes with which the ribs on each side coincide are oblique to the length of the ship, in order

Fig. 4.



that, on a horizontal plane, the proper curvature of the extremities may be obtained. The rib-timbers above the surface of the water are nearly rectilinear, but below that plane they are made with various curvatures. About the middle of the ship they have at bottom nearly the form of a semicircle, while towards the head and stern they form curves of contrary flexure, uniting on the keel with their lower concavities towards the exterior of the ship.

It may be observed that the keel of a ship is not horizontal, or parallel to the plane of floatation when the ship is in still water, but is made lower towards the stern than it is forwards, in order to allow greater length to the rudder, and thus increase the power of the latter in giving a direction to the ship's motion.

The keelson, *e e*, *fig.* 3, is placed longitudinally above the floor-timbers, and immediately over the keel, and it is united to the latter by bolts which go through both, and through the floor-timbers: its transverse section is represented at *s*, *fig.* 4. In large ships two additional keelsons, *t*, *t*, *fig.* 4, about thirty feet long, are bolted to the floor-timbers sufficiently near one another that the *step* (foot) of the mainmast may rest upon them; they serve to relieve the bottom of the ship from the pressure of that mast, and strengthen it against the upward action of the water. The timbers E and F, *fig.* 3, called the sternson and stemson, are also attached interiorly to the stern-post and stem-post, in order to increase the strength of the fabric.

The whole assemblage of rib-timbers is covered on the outside, and either wholly or partly on the inside of the ship, with planks of oak from three to six inches thick; and in order to make the latter bend so as to lie close to the curve surface of the ribs, they are, previously to being applied, moistened by steam: the exterior planking appears in the section, *fig.* 4. The planks are fastened to the ribs both by bolts and trenails (plugs of oak from one to two inches diameter), which pass quite through the ship's side, and are tightened by wedges driven into them at each extremity.

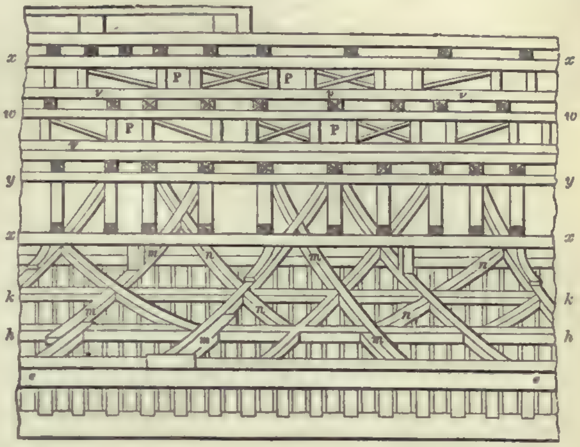
When the ribs do not join closely side by side, it is recommended that, before the planking is applied, the intervals both on the exterior and interior sides of the ship should be filled up with pieces of wood, as long as the curvature of the ribs will permit; the lines of junction with the ribs being well caulked. Sir Robert Seppings, however, proposed that for ships of war, where there are intervals between the principal rib-timbers, there should be introduced in those intervals other ribs extending from the keel up to the orlop or lower deck, since by this construction the lower part of the ship will be one compact mass of timber. He observed that the filling up of the spaces between the ribs not only adds to the strength of the ship by causing its bottom to have a solid thickness, but it tends to preserve the health of the crew, since those openings become receptacles for dirt, by which the air within the ship is vitiated. Channels, or water-courses, may be cut down the ribs at their interior lines of junction, and covered by planks or battens; by these channels the water is able to descend to the limber passage along the keel, and pass to the pump-well. For merchants' ships Sir Robert Seppings recommended strakes, or courses, of thick planks to extend longitudinally through the ship along the interior sides of all the ribs, and to cover the abuttings of the futtock-pieces in each alternate rib: such strakes appear at *n*, *o*, *p*, in *fig.* 4. He considered that no other interior planking would be required, but he recommended that battens should be fastened over the junctions of the ribs in the vertical planes.

A ship being a vast fabric consisting of comparatively short pieces of timber connected together by scarfing, and the principal parts of the frame-work, the ribs, the longitudinal timbers, and the planks being nearly at right angles to one another, it must of necessity happen that when the ship is not supported in its whole length and breadth, it will bend by its own weight. This will take place not only in the event of being lifted up by a wave under some place in its length, or pressed unequally by the force of a wave acting obliquely upon one bow or quarter, but even while floating in still water, from an excess of the weight in one transverse section over that in another. In this last case it has occurred, a horizontal line having been traced from head to stern by means of a spirit-level while the ship was on the stocks, that immediately upon the ship being launched the two extremities were observed to sink as much as three or four inches; the ends of the planks separating in the upper part of the structure, while the timbers below were in a state of compression, and the whole body of the ship becoming curved in a vertical direction. M. Dupin has shown ('Phil. Trans.,' 1817) that the strain is greatest at that transverse section of the ship which divides the whole length into two parts, in each of which the weight of the displaced fluid is equal to that of the corresponding part of the ship and its loading. To counteract the tendency to arch or bend was the object of Sir Robert Seppings in the application of diagonal braces to the interior side of a ship.

Trussing ships to prevent arching was used on the Continent as early as 1759; and the Swedish architect Chapman, who describes the manner of placing the trusses, speaks of the practice as being generally followed. The method consisted in setting up three parallel rows of fir-pillars from one end of the ship to the other; the middle row rested on the keelson, and the others on parallel longitudinal timbers, fastened by bolts to the ribs of the ship, one on each side of the keel; on the heads of these pillars in each row, and under the lower deck of the ship, was placed a longitudinal timber like an architrave; and diagonal braces were placed from the head of one pillar to the foot of the next in each of the three rows. It is evident that such a disposition of braces, if well executed, would serve to prevent or diminish the arching of the ship; but it is far inferior to the method now followed, because of the interference with the loading, and the liability of the pillars to be displaced in consequence of a violent movement of the ship.

In order to understand the construction of a ship and Sir R. Seppings's application of the braces, let *fig.* 5 represent a part, near the mainmast, of a longitudinal section through a large ship of war. In this figure *e e* is the top of the keelson; *h h* and *k k* are timbers extending through the whole length of the ship above the ribs, which are supposed to be close together, and not covered by an interior planking; *m m*, &c., are the principal timbers of the braces; *n n*, &c., are the trusses to those timbers; *x x* is a longitudinal shelf, on which rest the beams of the orlop deck, and the section shows how it is supported on the braces *m m*, &c.; *y y* is a like shelf, on which rest the beams of the lower gun-deck. The beams which support the upper decks rest likewise upon longitudinal shelf-pieces, which appear at *w w* and *z z*; and these lie upon chocks or upon pillars placed against the sides of the ship at intervals between the decks: the same shelf-pieces appear at *x*, *y*, *w*, *z*, in *fig.* 4. Through these and through the ribs pass the bolts by which the iron knees *r r r*, *fig.* 4, are attached to the body of the ship. In small vessels the beams are not always fastened by iron knees, but are merely coaked and bolted to the shelf-pieces: two or more iron knees are however usually placed under the beam near the main and fore masts. The shelves just mentioned constitute as many hoops connecting the ribs of the fabric together longitudinally; they are fastened by trenails and bolts to the ribs and to the beams of the decks: P P, &c., *fig.* 5, are the ports, and the dispositions of the braces between them are shown at *v v*, &c.

Fig 5.

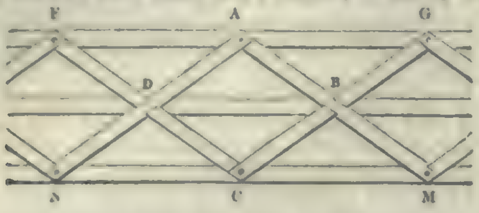


The connection of the two sides of the ship with each other is effected by means of the beams which extend under the decks from side to side. The tops of the iron knees are fastened to these, near their extremities, by bolts passing through them; and the lower parts of the knees are joined to the ship's side by bolts passing quite through the planking, the ribs, the chock-pieces, and the knees themselves. The beams of the principal decks in large ships are usually made in two pieces which abut end to end, and are connected together by having a strong middle piece scarfed and bolted to them. The planks of the gun and upper decks are recommended to be laid obliquely above the beams, and their outer extremities enter into a rebate formed near the interior side of the ship in certain longitudinal pieces which are channelled for the purpose of carrying off the water from the decks: the diagonal position is given to the deck planks, in order that they may increase the strength of the ship in a transverse direction. The exterior planking of the ship is laid on the ribs in longitudinal directions as nearly as possible parallel to the surface of the water; and at the extremities of the ship bolts pass obliquely through them and through the stem-post, the stern-post, and the adjacent rib-timbers.

The oblique timbers, or diagonal braces *m m*, &c. (*figs.* 4 and 5), which are about six or seven feet asunder, cross the ribs at angles of about 45°, and are placed in contrary directions from the middle of each side towards each extremity of the ship. Their upper ends abut against the horizontal shelf under the lower gun-deck, and their heels or lower extremities against the keelson, or against the horizontal timber on each side of it. These braces are attached to the timbers of the ship by cylindrical coaks and bolts, and the lower ends are connected with the keelson by iron straps. The timbers *h h*, *k k*, which are of fir, are attached to the sides of the diagonal braces; and the truss-timbers *n n*, &c., are placed diagonally across the rhomboidal space formed between the principal braces and the longitudinal pieces, in order to prevent the former from becoming bent by the compression which they may suffer endways from any strain which the ship may experience. The diagonal frames, together with the oblique trussing between the ports in the upper works, not only resist the tendency of the ship to become arched, but the former resist also any pressure which may take place externally against the bottom of the ship in the event of grounding; at the same time the exterior planking, the longitudinal timbers, and the oblique planking of the decks bind the whole fabric in one firm body. A close contact of the several parts of the diagonal frames is evidently of the utmost importance, as on it depends the security of the ship against a change of figure.

The principle on which the diagonal braces act may be easily understood from the following considerations:—Let A M, A N, *fig.* 6, be two principal braces; F D and D C, G B and B C, the struts or trusses inserted between them: then if C be the point of support, and if the parts beyond N and M be those which have a tendency to sink by the weight of the superstructure, it will follow from the elements of mechanics, that in this case the braces A M and A N, and the longitudinal timber F G, will be subject to the strain of extension in the direction of their lengths, while the trusses G B and B C, F D and D C, as well as the longitudinal timbers D D and M N, will be subject to the strain of compression. The effect of braces disposed in the positions A M, A N, in midships, and of others corresponding to them towards the head and stern, will be that the strain arising from the weight of the extremities of the ship, and by which arching is produced, is counteracted by the power of the trusses, in positions corresponding to F D and C G, to resist being compressed. A contrary effect would take place if the principal braces were disposed in the directions C F and C G, C being the point supported; for then the trusses between them, and the longitudinal pieces D B, would become disengaged, and would fall out of their places.

Fig. 6.



Sir Robert Seppings's diagonal braces were first introduced in 1810, and his paper on the application of them is contained in the 'Philosophical Transactions' for 1814. They were first applied to the Tremendous; and the success was complete, for after three years' service it was found, by means of lines of sights along the ship, that the gun-deck had not arched in the least, and the upper deck only three-fourths of an inch.

The introduction of iron knees and braces in wooden ships has not only strengthened them considerably, but is a great advantage in the saving of space for stowage. The sheathing of ships at first consisted of a second covering of planks applied, on the exterior of the first, over the bottom and sides as far as they were under water. [SHEATHING.] To save the first expense of copper, a mixed metal called Muntz's Metal, or yellow metal, and composed of 6 parts copper to 4 parts zinc, was in 1832 manufactured at Birmingham under patent, and its use has considerably increased in the merchant service. It has been found that there is a limit to the quantity of copper in this kind of sheathing, as unless the quantity of copper be between 50 and 63 per cent., and the zinc between 50 and 37 per cent., the compound will not roll at a red heat—while too much copper renders the compound difficult to work, and too much zinc renders it too hard when cold. By this use of metal sheathing shells and sea-weeds are partially prevented from adhering to the sides and bottoms; the friction of the water against them is diminished, and the damage which would be caused by worms is avoided.

As further details on the practice of wooden shipbuilding may be obtained from such excellent works as that of Mr. James Peake, of H.M. Dockyard, Woolwich, we only add some information on the manner in which various subjects intimately affecting the whole question of naval architecture have been treated.

In 1814, Mr. Walters, a civil architect, took out a patent for a method of counteracting the arching of a ship by braces of iron, which he proposed to apply on each side of the ship between the rib frames and the exterior planking. The braces were to extend obliquely both ways from the upper-deck beam in midships, in the direction of the line of shortest distance on the surface, towards the keel, where those which were on opposite sides of the ship were to meet under the bows and stern. By this disposition the extremities of the vessel could not sink without putting all the timbers between the trusses in a state of compression, and thus all their joints would be kept close together.

In the 'Mémoire de la Stabilité des Corps Flottants,' published in 1822 by the Baron Dupin, the stability of a ship as derived from difference of form was considered, and has proved useful to the shipbuilder.

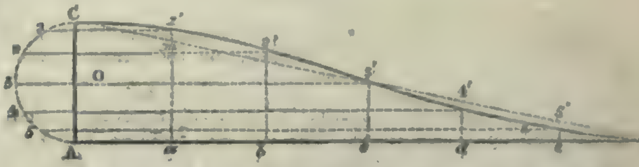
In about 1827, some papers, chiefly contributed by the students of the School of Naval Architecture at Portsmouth Dockyard, were published by Messrs. Morgan and Creuze, formerly pupils of that institution; and as these embodied several valuable translations from foreign authors on the laws of the resistance of fluids, they may still be read with considerable benefit. The Rev. Dr. Woolley, the late principal of that school, and our present great authority in naval mathematics, declared, in a paper read before the Institution of Naval Architects in 1860, that the experiments therein referred to were most carefully made, and entitled to rank among the most important contributions towards the determination of the theory which have ever appeared.

In 1851, Mr. Fincham, the master-shipwright at Portsmouth Dockyard, published a 'History of Naval Architecture,' which throws much light on various branches of the science.

In 1852, Lord Robert Montagu endeavoured, in a small work published by him on naval architecture, to influence the form of vessels by the dissemination of a new theory affecting the question of the molecular motion of water when disturbed by an advancing body. Something similar was also published at New York by Mr. Griffiths. But no permanent benefit to science seems to have been thereby produced; for, as already mentioned, the theory of resistances is still in a very incomplete and unsatisfactory state. The nearest approach to any theory founded on the disturbance of the particles of water is that of the form assumed by the *mass* of water so displaced, and which constitutes the theory announced to the scientific world in 1842 by Mr. John Scott Russell. This, as a question of shipbuilding, is one of paramount interest, intimately connected as it is with that of speed and the various other dependent qualifications of a ship, as influencing the ready defence of the country. Mr. Russell's theory has been already alluded to under RUSSELL, JOHN SCOTT, in the BIOG. DIV. of this Cyclopædia; but an illustration under SHIPBUILDING may be acceptable.

In devising the form of a ship, he proceeds, as already explained at *figs.* 3 and 4; but instead of adopting merely arbitrary changes of area, he arrives at his precise form of midship and load-water curves by the use of a simple and elegant formula, producing thereby curves of contrary flexure, which are said to facilitate the passage of a solid through a fluid. His experiments have shown that although the straight bow of wedge-like form presents actually the smallest surface to the friction of the particles of water, yet that in this form such particles, impinging upon the bow, rebound or are driven off at right angles to the water-line, raising a perceptible wave; while Scott Russell's curve of easy entrance allows the water to roll along the curve to the side of the vessel without such opposition. To illustrate plainly his theory with all possible brevity, let us suppose that, for instance, the area and outline curve of the midship section have been determined: this would represent the greatest beam, not at the centre of the fore and aft line of the ship, but at a point at about two-thirds of the length from the bow. Mr. Scott Russell divides his ship, upon the load water line, into two unequal and dissimilar portions. He considers that the length of midship portion (which, according to his theory, may consist of horizontal lines perfectly parallel to the keel) does not affect, or scarcely affects, any other property than the displacement, the additional friction of such added midship portion being comparatively trifling. Thus his ship, in its abstract original, is merely a bow and a stern; but as the curves which form these are, at their junction at the midship section, tangential, and are parallel to the longitudinal axis, they admit of an easy absorption into the general outline curve of the ship.

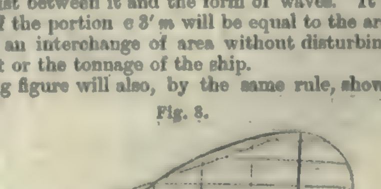
Fig. 7.



Let the line A B represent two-thirds of the whole length of the ship at the load-water line, and be the bow or forward portion, A C representing the half-breadth at her greatest or midship section: join C B. Bisect A C, and from its centre, O, and with O C as radius, describe the semicircle on A C, and divide it into any number of equal parts—say six, for example. Divide A B also into six equal parts, and draw the ordinates a 1', b 2', c 3', &c., parallel to A C. Then draw 1.1', 2.2', 3.3', &c., parallel to A B, meeting the first ordinates at the points 1', 2', 3', &c.; then will these points, 1', 2', 3', &c., be points in the curve which Mr. Scott Russell calls the wave principle, from some analogies which he considers to exist between it and the form of waves. It will be found that the area of the portion c 3' m will be equal to the area of the part 3' B n, forming an interchange of area without disturbing the amount of displacement or the tonnage of the ship.

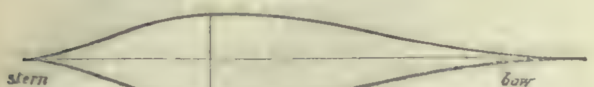
The following figure will also, by the same rule, show the shape of the stern portion of the load-water line, the outline curve being drawn in precisely the same manner.

Fig. 8.



In the figure below we have placed the two ends together (at a reduced scale), to show the whole load-water lines of the ship; and it is remarkable that, in vessels built on the wave principle, the amount of proportionate beam (within ordinary and reasonable limits) is said to very little affect the question of speed.

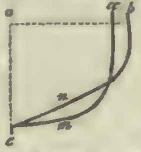
Fig. 9.



Another feature in Mr. Scott Russell's ingenious theory deserves mention. If we divide a ship vertically fore and aft into parallel portions of equal thickness, or, which may be more intelligible to the general reader, if we construct the model of such ship with boards of coloured wood of equal thickness throughout, the lines along the bottom of the ship, formed by the line of junction of such boards, and which are called buttock-lines, are made purposely cycloidal at the stern (the difference in the colour of the woods shows the lines more strongly): such a form of construction is said to facilitate the delivery of water as it passes along the hull.

Sir William Symonds, late surveyor of the navy, greatly altered the form of ships in her majesty's service, although he had much opposition to contend with. We are certainly indebted to him for more height between decks, faster sailing qualities, greater stability, but there are still those who do not wholly admit his theory as fully applicable to heavily armed ships. He gave greater beam, at the expense of hold stowage, &c.—the details of his construction may be seen in an interesting work bearing his name, published a few years since. As a comparison with the prevailing mode of constructing the midship form of section, the following figure will suffice.

Fig. 10.



If *o a* be the beam of a ship of war as usually constructed, he would increase the beam to *o b*, and adopt a very rising floor; while *a m c* would be the shape of the old form, *b n c* would be that of Sir W. Symonds; but this extent of beam has its limits, for although the displacement is taken from the bottom and placed at the load-water line, where it exerts a power of buoyancy, in the ratio of the square of its distance from the fore and aft midship line of the ship, it is said to render the rolling of a ship, under certain circumstances, less easy. But there is no question that shipbuilding received an impetus from Sir W. Symonds, at a time when in England the whole science was in a state of torpor.

Most elaborate investigations as to the mathematical principles involved in the rolling motion of a ship have been recently made by Dr. Woolley. Rolling is manifestly of two kinds, deep rolling and uneasy rolling; the vessel's motion in the latter case is principally affected by the raising of the centre of gravity and the suddenness of the check to oscillation caused by the rapid immersion of the lee-side of the ship, and is often sufficient to endanger masts, and is attendant upon the adoption of very rising floors, for the nearer the midship section approaches a semicircle, the deeper but easier will be the rolling, but this brings us into another extreme, namely, the possibility of danger from capsizing. Dr. Woolley has shown that the mathematical expression for periods of rolling, or as it is called, the theory of rotation, affords no correct indication of the actual condition of a vessel at such times of oscillation.

He gives the following formula:—

$$\text{Time of rotation} = \frac{\pi k}{\sqrt{g\,\mathrm{G}\mu}},$$

where k is the radius of gyration about a longitudinal axis perpendicular to the plane of rotation through the centre of gravity, and $\mathrm{G}\mu$ is the height of the metacentre above the centre of gravity. From which he deduces the following inferences, namely, the smaller the amount of $\mathrm{G}\mu$, or the less the stability of the ship, the longer is the time of oscillation, and consequently the greater the easiness of the motion; while such *case*, however, may, as already observed, be beyond a certain point a source of evident danger. Uneasy rolling may, moreover, be partially corrected by removing weights nearer to the side of the ship, thus increasing the axis of rotation, or as some call it the radius of gyration. The questions of rolling and stability are of great moment to the shipbuilder, as what are called sea-going qualities preeminently hinge on these. The well-known expression for comparison of stabilities is as follows, namely:—

$$\frac{2}{3}\int\frac{y^3\,dx}{\mathrm{D}}$$

when $\int y^3\,dx$ = the summation of the functions of the cubes of the ordinates, dx being the differential of the length of the elementary prism, and D being the displacement. So that in fact the comparative stabilities of ships may be said to be the comparative heights of their metacentres above the centres of gravity.

The rudder serves to govern the ship's motion; for, on being turned so that its plane is in a position oblique to the plane of the masts and keel, the reaction of the water against it as the ship advances, being resolved in a direction perpendicular to the last-mentioned plane, becomes a force which causes the ship to turn upon a line passing through its centre of gravity. Thus by giving the rudder more or less inclination to the said plane, the ship may be made to move in any required direction, or may be made to avoid an object by which its safety might be endangered.

Certain highly interesting facts have been very lately under discussion by the Institution of Naval Architects, aided by the opinions of naval officers of the greatest experience: these will be properly noticed under STEAM-VESSEL.

SHIPS AND SHIPPING. The law applicable to English merchant ships consists of so much of the common law as relates to personalty, the English maritime law to be found in statutes and decisions of her majesty's courts, and the general law maritime recognised less or more by all civilised nations, but peculiar to no one nation in particular. The subject may be conveniently considered under the following heads:—

1. The ownership of merchant vessels.
2. Their navigation.
3. The persons who navigate them.
4. The carriage of goods and passengers.

1. *Ownership. Acquisition of Ship Property.*—Ships, or shares in them, are, in view of the law of England, personal property, which upon the death of the owner passes to his personal representative, and on marriage of a female owner to her husband. Ship property is legally acquired by construction, by purchase, or by capture from an enemy. Very often, perhaps most frequently, the keel of a new ship is not laid down in the builder's yard before a contract has been concluded for her construction between the builder and his customer. Usually, however, all property in the uncompleted vessel continues meanwhile to be vested in the builder, notwithstanding such contract, even although payments be made in advance, and appear to be regulated in accordance with the progress of the work. It is not till she is completed and ready for delivery, and either delivered or approved of, that the rights of ownership vest in the purchaser. Before that time, any instrument executed on his part, with the intention to transfer a title to the ship or any share of her, would be a mere nullity. It is, however, allowed by the law of England to stipulate for a transfer of the property in the uncompleted ship at any stage of her progress, in return for payment of the price in advance by certain agreed instalments; and this is sometimes done.

Purchase of ships already built presupposes in the buyer much skill and no small degree of caution to be perfectly safe. The policy of law in this country respecting bargains is to throw the buyer entirely on his own resources in making the contract, by cutting off all hope of subsequent help out of difficulties into which he never could have fallen if he had used his reason at the time of the purchase. Moreover the difficulties in the way of a purchaser's retrieving himself in case of a bad bargain are increased by the recent statutes respecting the transfer and registration of merchant ships (17 & 18 Vict. c. 104; 18 & 19 Vict. c. 91). A compulsory form of bill of sale is prescribed by the statute, any deviation from which, by the introduction of other particulars, may deprive the buyer of the right of requiring the registration of his title. Warranties, therefore, and representations in the nature of warranties, cannot now be introduced into the only document of contract that can be enforced in a court of law or equity. For any contract, however formal and solemn, other than the authorised bill of sale, although duly executed by both parties, and money paid upon it, gives the buyer no legal or equitable title to the ship, no right to sue in a court of equity for specific performance, or even any right to sue for damages in a court of law on non-performance. This appears to be thought indispensable to any system of effective registration of titles to ship-property.

Registration.—All British ships are now required to be registered, excepting only ships of fifteen tons burden and under, employed on British rivers or coasts, and vessels of thirty tons, not having a whole or fixed deck, and employed in fishing off the coasts of British North America. A British ship is no longer necessarily a British-built ship, or a British-manned ship, but simply a British-owned ship. The persons who are capable in law of being owners of a British ship are (1), natural born British subjects; (2), persons made denizens by letters of denization, or naturalised by or pursuant to any act or ordinance of the Imperial Legislature, or by or pursuant to any act or ordinance of the proper legislative authority in any British possession, provided that while they are such owners they are resident within her majesty's dominions, or members of a British factory, or partners in a house actually carrying on business in the United Kingdom or within the British dominions, and have taken the oath of allegiance subsequently to denization or naturalisation; and (3), bodies corporate established under, subject to the laws of, and having their principal place of business in, the United Kingdom or some British possession. For the purpose of registration, a declaration of ownership is required from the applicant, whose qualification to be the owner of a British ship is thereby ascertained; and any ship sailing under British colours after a disqualified person has become one of her owners is liable to be forfeited and seized into the possession of the crown. Any person making a false declaration as to the qualification of the applicant, forfeits all right which he, or such applicant if cognisant of the offence, possesses in the ship.

A British ship is supposed in law to be divided into sixty-four shares. No one can be registered as owner of a fraction of a share; and no more than thirty-two persons can be separately registered as owners of the ship at one time. Yet a corporate body, no matter how many persons are members of it, is registered as one person: and any five individuals may be registered jointly for the same share or shares, so as to count for one person on the register and no more. If six individuals therefore were to purchase one share, no more than five could appear on the register; the sixth would be a beneficial owner only, and for the purposes of transfer must apply to the five in whom the title is vested. Upon registration of a ship being completed, a certificate of registry is given, indorsed with the particulars on the register; but instead of being, as it was before, the document of title to the ship, it is now no more than is implied in the name, a certificate that the vessel is British-owned and registered, and as such is to remain in the keeping of the master for the purposes of the navigation of the vessel.

The document of title is now the register; all who appear on that book as owners continue to retain the title so declared to be in them as long as they are suffered to remain there, with full power to convey title to any other, and to give valid and effectual receipts for the price. It is not therefore the execution of the authorised bill of sale that secures the property to a purchaser; that bill of sale must be registered, and the burden of that duty is imposed on the most willing shoulders connected with the transaction, namely, those of the buyer himself.

Mortgages of the ship, or any shares of it, are also allowed to be registered, but not trusts or any notice of them. Now as this important book is entirely local, and the necessities of trade might often require the sale or mortgage of the vessel to be effected in a foreign country, or at a distant port in her majesty's dominions, some contrivance was necessary for placing the contents of the register in all their integrity and legal effect before the eyes of the intending purchaser or lender at a distance. This is effected by means of a certificate of sale, or a certificate of mortgage, which is issued upon application by the registrar, containing an exact copy of the details on the register as they appear at the moment of issue. The purchaser or lender is thereby informed of the exact state of the title which is offered, and how far the property is already burdened, if burdened at all. By indorsement on this certificate his title is secured to him, as effectually, and with the same consequences, as if it had been placed on the register at the time when the certificate was granted; and the mortgage takes rank before all other mortgages effected after the issue of the certificate, and not effected by means of it.

Title by Capture.—Title by capture is an acquisition that cannot be made except during war; for capture is the exercise of a belligerent right. But even when exercised during the existence of a war, no more than an inchoate right of property in the captured ship is vested until the capture is succeeded by condemnation in accordance with the principles of the law of nations by a court of competent jurisdiction, sitting by authority of the sovereign of the captors, either in the country to which they belong or in that of an ally in the war. The vessel at the time of condemnation must be lying in a port of that sovereign, or of such ally; for condemnation of her whilst lying in the port of a neutral country, except under very peculiar circumstances, is, according to the English law, a nullity; but the law of the United States appears to differ in that respect, and to have the support of continental practice during the wars at least that followed the first French revolution.

Forfeiture of Ship Property.—Any disqualified person improperly obtaining and continuing to hold shares in a British registered ship, forfeits his shares in consequence; and any ship owned wholly or in part by a person who is disqualified under the law of this country, which assumes the British flag, except for the mere purpose of escaping capture by an enemy, is forfeited to the crown. If any master, for the purposes of his ship, use a British certificate of registry which has not been legally granted in respect of that vessel, he is himself guilty of a misdemeanor, and the ship is thereby forfeited. If anything is done or permitted by the master or owner of a British ship with intent to conceal her British character from any person entitled by British law to inquire into the same—or with intent to assume a foreign character—or with intent to deceive any person entitled to inquire into her national character whilst making such inquiry, and in respect thereof, the ship is thereby forfeited. These forfeitures are authorised by the Merchant Shipping Act of 1854. By the Passengers Act of 1855 (18 & 19 Vict. c. 119) it is enacted that any vessel clearing out to sea without the requisite bond being first executed by the master, or without the requisite certificate of clearance being first obtained, is forfeited to the crown in consequence.

Legal Rights of Part-owners.—If the ownership of a vessel acquired originally in one or other of these ways is not vested in a single person, the several owners, considered as among themselves and not in relation to the register, may hold the vessel in partnership. This, however, is very seldom the case. Usually they are part-owners merely, and as such have no authority by law, any one of them, to bind the rest by his contracts on account of the ship. But if they agree to undertake a trading adventure with the vessel, although they still remain as before, mere part-owners in respect of the hull of the ship, they are partners in the adventure. They are bound to contribute in that case to the expense of the outfit, as being in the nature of capital for the enterprise; and they are entitled to an account at the end of the voyage when the adventure is finished.

The majority in value of the owners of a vessel being authorised by the English law to employ the ship "upon any probable design," are only entitled to do so upon giving security to the minority in a sum equal in value to the united shares of the latter. The mode of obtaining this security is by procuring a warrant from the court of admiralty for the arrest of the ship. After the security has been given, the minority do not share either in the expenses or profits of the adventure. If no application of this kind is made to the court, the minority ought expressly to give notice of their dissent both to their co-owners and all other parties engaged in the proceedings, and they will then be relieved from the necessity of contributing in case of a loss. If they take no steps of the kind, their co-owners, as in the case of any other chattel possessed in common, will not be responsible to them for any consequences short of an absolute destruction by their means of the ship. The same proceedings are proper to be taken where the co-owners are equally divided in opinion, or the minority have obtained possession of the ship. The application for the arrest should be made at the earliest stage of the proceedings, because otherwise the applicant will be held liable to contribute to the previous expenses although he will receive no part of the profits, or even have his application to the court altogether refused.

Agents of the Owners.—For the purpose of managing the ship it is very usual for the owners to concur in appointing an agent who is known to the world thereafter as ship's husband. His powers are very large, considered in the light of the duty for which he is appointed, which is to attend to all matters connected with the outfit and freighting of the ship. It is not, however, within the limits of his authority to effect an insurance. If he make any advances, he can sue those part-owners on whose behalf the advances are made for what is due to him. In case of disagreement among the part-owners as to the settlement of accounts concerning the expenses and earnings of a ship, the ordinary remedy is by a suit in equity.

Another agent who is endowed with very extensive power under certain circumstances to bind the owners by his contract, is the master of the ship. He has power to bind the owners by entering into engagements with third parties relative to the employment of the ship. Such engagements are of two kinds:—1. A contract by which the whole ship is let to hire during an entire voyage, which may be accomplished by a charter-party under seal, or by memorandum of charter-party not under seal. 2. A contract with distinct persons to convey the goods of each, in which case the ship is called a general ship. Such contracts made by the master, being within the lawful scope of his employment, are legally considered to be made by the owners who employ him; and in either case they or the master are liable in respect of these contracts. If the charter-party is made under seal and in the name of the master only, it will not support a direct action upon it against the owners. Still if the contract is duly made, that is, within the usual employment of the master, and under such circumstances as afford either direct proof of authority or evidence from which such authority may be inferred, the owners may be made responsible either by a special action on the case or by a suit in equity. But the master cannot be assumed to have a power to annul an express contract entered into by the owners themselves and to form a fresh contract with other parties.

Besides this power which the master has to bind the owners by his contracts relative to the lading of the ship, he has also authority to render them liable for repairs done and provisions and other things furnished for her use, or for the money which he has expended for such purposes, if they were necessary. In this case also the remedy of the creditor is against the master, unless by express contract he be exempted, and also against the owners. If the contract is made by the owners themselves, they alone are liable. The English law does not follow the rule of the civil law, by which a party who had repaired or furnished a ship had a claim on the ship itself in preference to all other creditors. A party who has done repairs upon a ship has a right to retain the possession of it until his demands are paid; but if he gives up possession, he is on the same footing as other creditors. Where repairs have been done, or necessaries supplied to a ship, the legal owners, although there be proof of their title to the ship, are not on that ground presumed to be liable. There is no presumption of law upon the subject; the matter is altogether a question of evidence; and the question to be decided, in order to determine the liability, is upon whose credit the work was done or the necessaries supplied. If a ship is let out for hire, the owners are no more liable for the work done by order of the hirers, than a landlord of a house would be for work done by order of his tenant. Analogous observations are applicable with respect to the liability of mortgagees and charterers. Where there is an actual letting of the whole ship, and the lessee has the entire control and management of her, the master and mariners being subject to his orders, the lessee becomes for the time invested with the character of owner. But where by the terms of the contract the master and mariners continue subject to the owner, and he through them retains the control and management of the ship, the contract is merely for carrying the lessee's goods.

When, however, the ship is abroad, and the necessary expenses cannot otherwise be defrayed, the master has the same power which the owners or part-owners to the extent of their shares under all circumstances have, to hypothecate the ship and freight as a security for debts contracted on behalf of the ship. The contract of hypothecation is called a contract of bottomry, by which the ship upon its arrival in port is answerable for the money advanced, with such interest as may have been agreed on. By the terms of the contract the repayment of the money is made to depend upon the accomplishment of the voyage, and, in consideration of the risk, the lender is permitted to charge a high rate of interest. By such hypothecation the creditor acquires a claim on the ship. [BOTTOMRY.] When the claim has been created by the master abroad, it may be enforced by suit in the Admiralty Court; but if the ship has been hypothecated by the owners at home, the parties can only have recourse to the common law or equity courts. The Admiralty and the equity courts will recognise the interest of the assignee of a bottomry bond, though at common law he cannot sue in his own name. In general the master has been held not to be authorised to raise money on bottomry within any part of the same country where the owners reside, on the ground that it is his duty to communicate with them before entering into such a contract. But where by reason of hostilities communication with the owners was almost impossible, and immediate necessity existed for the money, which could not be procured otherwise than upon bottomry, a master was held to have authority to raise it on those terms. When money is lent on bottomry, the owners are not personally responsible. The credit is given to the master and the ship, and the remedy is against them only. The master cannot hypothecate the ship for a debt of his own, nor can he give a bottomry bond for matters not within the scope of his authority. If the sums secured by the bond are not repaid, an application must be made to the Court of Admiralty, founded on the instrument of contract and an affidavit of the facts, upon which a warrant issues to arrest the ship, and the persons interested are cited to appear before the court, which then decides what is to be done. If several bonds have been given at different times, the latest in point of time is entitled to be first satisfied, a rule derived from the civil law. ('Dig.' 20, tit. 4, s. 5, 6.) If the necessary amount of money cannot be raised by hypothecating the ship and freight, the master may also sell part of the cargo or pledge it.

Under those circumstances of unavoidable necessity which would authorise the hypothecation of the ship and freight, the master has authority in case of need to hypothecate the cargo for the purposes of the voyage. He may always in these circumstances sell a part of the cargo. He is never allowed to sell the whole for the professed purposes of the adventure, as the adventure is by that very act put an end to; but in case of damage to the cargo, which threatens the destruction of the whole of it before his arrival at the port of destination, he may justify selling part or even the whole, as the only means of saving something for the advantage of the proprietors. To hypothecate the cargo for the purposes of the cargo and the advantage of the proprietors, is within the extent of his powers under proper circumstances, and such a bond executed by the master only is available to the holder by the process of the English Court of Admiralty. To sell the ship is the last conceivable act of a master in circumstances of extreme distress. He will not be justified in doing so, nor can he give the purchaser a good title, if she can be repaired and he has the means and opportunity of doing so, under circumstances in which a judicious man would take that course. But to justify such an act, and make it a binding transfer of property to another, the distress must be so extreme, under circumstances so destitute of assistance, or so void of all occasion for wishing assistance, that either a faithful man can find no better remedy, or a judicious man can wish no other.

Limitation of Liability of Owners.—The liability of the owners under certain circumstances is either limited or altogether taken away by the law of this country.

No owner of any British sea-going ship, or share therein, is liable to any extent whatsoever for loss or damage happening without his fault or privity: 1, of or to any goods, merchandise, or other thing whatsoever taken in, or put on board any such ship, by reason of any fire happening on board such ship; 2, of or to any gold, silver, diamonds, watches, jewels, or precious stones, taken in, or put on board any such ship, by reason of any robbery, embezzlement, making away with, or secreting thereof, unless the owner or shipper thereof, has, at the time of shipping the same, inserted in his bills of lading, or otherwise declared in writing to the master or owner of such ship the true nature and value of such articles.

Where all or any of the following events occur without his actual fault or privity; namely, 1, where any loss of life or personal injury is caused to any person being carried in such ship; 2, where any damage or loss is caused to any goods, merchandise, or other things whatsoever on board any such ship; 3, where any loss of life or personal injury is by reason of the improper navigation of such sea-going ship caused to any person carried in any other ship or boat; 4, where any loss or damage is by reason of any such improper navigation of such sea-going ship caused to any other ship or boat, or to any goods, merchandise, or other things whatsoever, on board any other ship or boat; no owner of any British sea-going ship or share therein, is answerable in damages to an extent beyond the value of his ship and the freight due, or to grow due, in respect of such ship during the voyage which at the time of the happening of any such events is in prosecution or contracted for, subject, however, to this proviso, namely, that in no case where any such liability is incurred in respect of loss of life or personal injury to any passenger is the value of any ship and the freight thereof to be taken as less than 15*l.* per registered ton. The benefit of these provisions is not obtainable, even in our courts, by any foreign ship, nor is it available for a British sea-going ship when sued for injury done by her to a foreign vessel, unless at the time of the accident both ships were in British waters.

2. *The Navigation of Ships. Rules of the Sea.*—For the government of ships in their course over the sea, convenience and necessity early gave rise to certain accustomed practices which have ultimately resulted in rules that are known as the rules of the sea. Those rules, which are still recognised by all maritime nations, were set forth in a notice published by the Trinity House on the 30th October, 1840, in the following terms: "The recognised rules for sailing-vessels is, that those having the wind fair, shall give way to those on a wind; that when both are going by the wind, the vessel on the starboard tack shall keep her wind, and the one on the larboard tack bear up, thereby passing each other on the larboard hand; that when both vessels have the wind large or a-beam, and meet, they shall pass each other in the same way on the larboard hand, to effect which two last mentioned objects, the helm must be put to port." Steam-vessels, for the purposes of these rules were regarded as vessels navigating with a fair wind, and were to give way to sailing-vessels on a wind on either tack. With regard to steamers passing each other, it was at that time the rule that each should put her helm to port, and in narrow channels that a steamer should always leave the vessel she is passing on the larboard hand.

The rules already given are still in force on the high seas among other nations, and consequently must be observed also by British ships when passing a foreign ship. It seemed good, however, to the British parliament to introduce new rules into the Merchant Shipping Act of 1854, which are now compulsory on all British vessels when passing each other. These rules are the following: 1. "Whenever any ship, whether a steam or sailing ship, proceeding in one direction, meets another ship, whether a steam or sailing ship, proceeding in another direction, so that if both ships were to continue their respective courses, they would pass so near as to involve any risk of a collision, the helms of both ships shall be put to port, so as to pass on the port side of each other. This rule shall be obeyed by all steam-ships and by all sailing-ships, whether on the port or starboard tack, and whether close-hauled or not; unless the circumstances of the case are such as to render a departure from the rule necessary in order to avoid immediate danger; and subject also to the proviso, that due regard shall be had to the dangers of navigation, and as regards sailing-ships on the starboard tack close-hauled, to the keeping such ships under command. 2. Every steam-ship, when navigating any narrow channel, shall, whenever it is safe and practicable, keep to that side of the fair-way or mid-channel, which lies on the starboard side of such steam-ship."

A code of rules respecting the exhibition of lights on board, and the use of fog signals, has been published by the Admiralty under the authority of the statute. Steamers between sunset and sunrise are to exhibit a bright white light at the foremast head; a green light on the starboard side, and a red light on the port side, except that when they are proceeding under sails only, the light on the mast is to be dispensed with. Sailing-vessels are to exhibit the red and the green side lights in accordance with the above rule, but no white light on the mast. Pilot vessels are to carry only a white light at the mast-head, and to exhibit a flare-up light every fifteen minutes. Sea-going vessels at anchor in roadsteads or fair-ways, must exhibit, on a conspicuous part, not more than 20 feet from the hull, a white light in an eight-inch globular lantern. As fog signals, sailing-vessels when under way, are in all cases of fog required to use, when on the starboard tack, a fog-horn, and, when on the port tack, to ring a bell, sounding the one or the other respectively, once at least every five minutes; and steamers when under way and their steam up, are to use a steam-whistle before the funnel, sounding it once at least every five minutes; but when their steam is not up they are to use a fog-horn or bell, as in the case of sailing-vessels.

Collisions.—Notwithstanding these rules for the guidance and protection of ships in their progress at sea, and in the fair-ways of maritime traffic, collisions do occur, and questions of fact, difficult to determine, arise as to the existence of negligence in either vessel or in both. It would be quite impossible here to enter upon a detail of cases illustrative of this part of the law. Those who are desirous of considering the subject when exhibited in the occurrences of maritime life must consult those works, the titles of some of which we have appended to this article, in which every help is offered to a complete comprehension of the principles of the law, and their application to facts. The leading rules, however, of the law on this subject may here be succinctly set down. Those of the general maritime law are these, namely, 1, when the injury occasioned is the result of pure accident, the loss lies where it fell; 2, if both parties are to blame, the loss is divided between them; 3, if it happen through misconduct of the suffering party only, he bears his own burden; 4, if it be entirely the fault of the other vessel, the sufferer is entitled to complete compensation for his loss.

By the Merchant Shipping Act of 1854, these rules underwent considerable modification, and since then the British maritime law, which had previously differed from the common law on the subject of negligence, is now identical with it. At common law, a person cannot recover for damage sustained from the negligence of another if his own negligence contributed to the event, or if he might have avoided it by the exercise of ordinary care and skill; but if the other who is sued might, by ordinary care and skill, have avoided the accident, he is liable, notwithstanding there be negligence in the plaintiff remotely connected with the event.

In case of damage done to a ship by another vessel that is in fault, the maritime law gives to the sufferer a lien on the ship that does the wrong. In virtue of that lien, she may be arrested under process of the Admiralty Court, condemned, and sold, and so much of the proceeds of sale applied as is necessary to compensate the owner of the damaged ship; and in case the produce of the sale is not sufficient, the lien extends to the freight being carried by the vessel at the time, and that too may be ordered to be brought into the treasury of the court for adjudication and distribution, pursuant to the law and facts of the case. We have already seen that the liability of British owners is limited, under the supposed circumstances, to the value of the ship and the amount of the freight.

Pilotage; Tonnage.—Immediately connected with the subject of damage by collision is the law of the local pilot. The legislature has made it compulsory on vessels passing over certain pilotage grounds to take one of the local licensed pilots on board, and has at the same time conferred upon the owner, who was thus deprived of his option, an immunity from liability for any damage caused by the ship while she is under the management of such pilot, provided the damage is in no degree attributable to misconduct in the master and crew, or insufficiency of the ship's equipment. The institution of pilots in this country dates from the time of Henry VIII.; and their government is entrusted to the Trinity House, and to certain other pilotage authorities throughout the United Kingdom. It is binding on a pilot to take charge of a ship when required, and on a master to receive such pilot on board when he offers within the pilotage ground, there being at the time no licensed pilot on board. When the pilot takes charge of the ship he is supreme, the master and crew being bound to obey him in all reasonable orders and demands. If the ship is at the time in tow, the tug also is under the orders of the same pilot; and it may be presumed concerning the tug in tow, that if she obey exactly the orders of the licensed pilot in the ship, the owners of the tug are not liable for any damage resulting in consequence. Under these circumstances, it is the pilot who is liable, and his liability in the Trinity House district is limited by Parliament to the amount of his bond, namely, 100*l*. The duty of taking such pilot on board in these particular localities being compulsory on foreign as well as British ships, they participate also in the immunity conferred on the others. [PILOT.]

3. *The Persons who Navigate British Ships. Qualification of Officers.*—A very important change was introduced into the mercantile marine of this country by the Merchant Shipping Act of 1854: the officers of that service are now intrusted with command only upon satisfactory evidence of their qualifications and fitness. Upon testimonials of service, experience, and character, and upon personal examination of the candidates in various departments of knowledge proper to their calling, do the local marine boards distributed throughout the United Kingdom, at all ports of any note, determine week by week upon giving or refusing certificates of fitness to be masters, mates, or first or second mates of foreign-going ships or home-trade passenger ships. These are certificates of competency. Certificates of service as master or mate in British foreign-going ships before the 1st of January, 1851, or as master or mate of a home-trade passenger ship before the 1st of January, 1854, entitle the holders still to serve in the like capacities. A lieutenant, master, passed mate, or second master, or one of any higher rank in her majesty's service, or that of the East India Company, is entitled to serve as master of a British ship. A certificate proper to the rank in which he serves must be held by and be in the possession of the master and first and second or only mate of every foreign-going British ship, and the master and first or only mate of every home-trade passenger ship proceeding to sea from the United Kingdom, otherwise she cannot clear out. And in every such vessel of 100 tons burden and upwards there must be at least one officer besides the master who possesses a legal valid certificate appropriate to the grade of first or only mate of such vessel, or to a higher grade. A penalty of 50*l*. is laid on every one who goes to sea as officer without an appropriate certificate, and on every person who employs anyone to go to sea in such capacity without first ascertaining whether he is so qualified.

Masters' Duties, Powers, and Rights.—In the responsible situation of master of a British merchant ship, his duties are very numerous, onerous, and important. The ship and her cargo are committed to his care, and he is to see that neither take any damage, so far as provident skill and vigilance can prevent or the use of vigorous means can repel. But when prevention is already become impossible, he is then to use all diligence and means in his power to repair the damage, as any judicious man would do for his own property. He keeps his owners constantly informed of his whereabouts, and of the events and incidents of the voyage, enabling them on each occasion to take measures for their own protection and benefit, as they might be advised. He is to give his whole time to their service, and account to them faithfully on his return. The ship's log and official log must be kept under his supervision.

It is his duty to provide for the sustenance, comfort, and health of all persons on board; and if injury accrue through negligence of his in not providing stores, medicines, or proper accommodation, he is liable to an action. His authority on board while at sea is supreme and despotic; and if there be disobedience on the part of the crew, he may correct them in a reasonable manner. On all occasions when discipline is infringed, he will be careful to inquire and inform himself of the true state of the facts before he visit any one with punishment, unless the breach of duty or discipline is obvious to his eyes, and the offence is of that mutinous character which must be checked on the instant with force. He is responsible on his return for all his conduct on board towards others, either on prosecution by public law or at the suits of private persons who have suffered injury at his hands.

His conduct is also liable to be inquired into by the Board of Trade, who have power, if there be occasion, to withdraw his certificate, or by a naval court on the high seas or abroad, who may discharge him and put another in his place.

For his wages, he now has the same lien on the ship and remedies as a common seaman. His disbursements, however, form a mere personal debt. His powers as agent of the owners have already been noticed under the first division of this article.

The Seamen. Ship's Articles.—Apprentices are to be indentured; seamen for foreign-going ships must—and seamen for home-trade ships may—be engaged and discharged before a shipping-master. The agreement of hiring is to be in writing, according to the form, and containing at least all the stipulations, prescribed by the statute. Other stipulations may be added by the consent of both parties; but "no seaman shall by any agreement forfeit his lien upon the ship, or be deprived of any remedy for the recovery of his wages to which he would otherwise have been entitled; and every stipulation in any agreement inconsistent with any provision in this Act (17 & 18 Vict., c. 104), and every stipulation by which any seaman consents to abandon his right to wages in the case of the loss of the ship, or to abandon any right which he may have or obtain in the nature of salvage, shall be wholly inoperative." Although this agreement is in writing, and signed by the seaman, he may prove his case in a court of law without producing or giving notice to produce it; and any erasure, interlineation, or alteration in it, not proved to have been made with the consent of all the persons interested in the change by the written attestation, if made in her majesty's dominions, of some shipping-master, justice, officer of customs, or other public functionary, or, if made out of her majesty's dominions, of a British consular officer, or where there is no such officer of two respectable British merchants, is wholly inoperative. Allotment notes must be stipulated for if required, and may only be granted in favour of the seaman's wife, father, mother, grandfather. grandmother, child or grandchild, or sister or brother; the statute expressly providing that these and these only shall have a right of action on the note. The agreement must contain the following particulars, namely (1), the nature and, as far as practicable, the duration of the intended voyage or engagement; (2), the number and description of the crew, specifying how many are engaged as sailors; (3), the time at which such seaman is to be on board, or to begin work; (4), the capacity in which each seaman is to serve; (5), the amount of wages that each seaman is to receive; (6), a scale of the provisions which are to be furnished to each seaman; (7), any regulations as to conduct on board, and as to fines, short allowances of provisions, or other lawful punishments for misconduct, which have been sanctioned by the Board of Trade as regulations proper to be adopted, and which the parties agree to adopt. Any fresh stipulation on the part of the seamen with the master in the course of the same voyage for an advance in the rate of wages, or for any special gratuity, cannot be enforced, unless the circumstances existing at the time be such as to have cancelled the agreement already made.

Wages.—Wages are no longer dependent on the earning of freight: They may not be attached; and payment of them to the seaman is valid and effectual, notwithstanding any prior attachment, incumbrance, or arrestment thereon, or assignment thereof.

The amount of wages due to the seaman if he fulfil his contract is the full amount originally stipulated therein to be paid him. The voyage, however, is liable to interruption by various casualties; the service of the seaman is subject to discontinuance before the termination contemplated originally on both sides; and it is not a very easy matter in general language to lay down the law which is applicable to each case before it arises. It is not in the power of the master, by wrongfully dismissing any of his crew in the course of the voyage, to deprive them of all or any part of their wages; they may recover the whole, subject to the deduction of such wages as they have earned elsewhere during the period claimed for. But if the ship be lost, or if the mariner quit the vessel for the purpose of taking service in her majesty's navy, he is entitled to the wages due up to the interruption of his service. By desertion, however, or misconduct of a flagrant and serious character, he may forfeit all right to wages. In case death put a period to his service on board during the voyage, it seems his representatives are entitled to be paid wages up to the day of the death, unless the contract made with the owners be such that no right accrues if the seaman do not navigate the ship to the port of destination. The French code, more liberal than our own law, where the hiring is for the voyage, directs payment of half the stipulated amount if the seaman dies on the outward voyage, and the whole if the death happens during the homeward passage.

In virtue of the maritime law the seamen have a lien on the ship for the amount of their wages, which enables them by process from the Court of Admiralty to arrest the vessel, and, unless the owners interpose to pay their just demand, to sell her after sentence of condemnation. The Merchant Shipping Act of 1854 confers the same advantage on the master, who till then had no such remedy. The jurisdiction of the Admiralty Court, however, in claims for wages, is restrained to the case of a contract in the ordinary terms, and not under seal; for if either it be made under seal, or be special in its stipulations, it cannot be the subject of a suit in that court, at the peril of a writ of prohibition issuing from the courts of common law. A further restriction on that jurisdiction is placed by the statute, which prohibits any suit for the recovery of wages, when the sum is under *50l.*, from being instituted in any Court of Admiralty, Vice Admiralty, the Court of Session in Scotland, or any of the superior courts within her majesty's dominions, unless the owner of the ship is adjudged bankrupt or declared insolvent; or unless the ship is under arrest, or is sold by the authority of any such court; or unless any justices, acting under authority of the statute, refer the case to the adjudication of such court; or unless neither the owner nor master is or resides within twenty miles of the place where the seaman or apprentice is discharged or put ashore. In lieu of this, the seaman is now enabled to proceed summarily before any two justices of the peace, or one stipendiary magistrate acting in or near the place at which the service is terminated, or at which the discharge takes place, or, in Scotland, before any such justices or the sheriff of the county, for any sum not exceeding *50l.* over and above the costs. When the engagement is to terminate in the United Kingdom he is not entitled to sue for his wages in any court abroad, unless he be discharged with the sanction of the shipping master, chief officer of customs, British consular officer, or two respectable merchants in or near the place, and with the written consent of the master; or unless he prove such ill-usage on the part of the master, or by his authority, as to warrant reasonable apprehension of danger to life. On his return, however, if he prove either such ill-usage or other misconduct on the part of the owner or master as would have entitled him but for the statutory prohibition to sue for wages before the termination of the voyage, he is entitled, besides his wages, to compensation not exceeding *20l.* in amount.

Discipline. Protective Laws.—We have already seen the authority which is reposed by the law in the master for the maintenance of discipline on board. His power necessarily enables him to inflict punishment for smaller offences upon the instant. In case of the greater offences his power goes no further than to put the seaman, if need be, in confinement, in order to deliver him up on reaching land to the proper authorities, for investigation of the charges made against him, and the consequences which ought to follow thereon. The statute has ascertained the amount of punishment to be inflicted in certain particular cases by the magistrate. The Board of Trade, in certain lesser offences, enables the owners and seamen to agree upon the penalties which the Board have recommended as reasonable and proper to be adopted, and have set out in a schedule published by them in pursuance with their authority under the Act. But no conviction under the Merchant Shipping Act may be made in any summary proceeding, unless such proceeding is commenced within six months after the offence was committed, or within two months after both parties arrive or are at one time within the United Kingdom, or within the jurisdiction of any court capable of dealing with the case in a British possession. Nor can any order for the payment of money be made in a summary proceeding, unless such proceeding is within six months after the cause of complaint arose, or after both parties arrive or are within the United Kingdom, or within the jurisdiction of any court in a British possession capable of dealing with the case. Any local jurisdiction situate on the coast of any sea, or abutting on or projecting into any bay, channel, lake, river, or other navigable water, is extended by the Merchant Shipping Act to any ship or boat being in or lying or passing off such coast, or being in or near such bay, channel, lake, river, or navigable water, and to all persons on board or for the time being belonging thereto, as if such ship, boat, or persons were within the limits of the original jurisdiction. And every offence is to be deemed to have been committed, and every cause of complaint to have arisen, either in the place it was committed or arose, or where the offender or person complained against may be.

The ship's stores, the water on board, and the medicine chest, are subject to inspection by certain public officers. The seaman may complain of the stores and have them inspected, at the peril however of being mulcted in one week's wages in case his complaint be frivolous. In case he is kept on short allowance, not in the way of punishment nor through any fault of the master, but solely from those accidents of the sea that may delay the best provisioned ship that sails, he is entitled to a certain compensation per day while the deficiency lasts. This is rather in the way of wages to him. If he were to be injured, however, by deficiency or badness, either of the stores or medicines, where there is negligence in the master, his right of action for damages is clear. A seaman is not entitled to bring an action because the vessel was unseaworthy and he suffered by it; yet, as the statute provides for his being well and comfortably accommodated, any defect of the ship that should form an encroachment upon such statutory right would be a good ground of action to any seaman suffering injury thereby.

Medicines and medical assistance on board are supplied to the seamen at the owner's expense; and so must they be, also, together with subsistence, if the patient is removed from on board to prevent infection, or otherwise for the ship's convenience, in case he subsequently return to duty on board. If the sickness be the result of injury received in the service of the ship he must be supplied by the owner with medical advice and medicines, subsistence and attendance, until he is cured, or dies, or is brought back to some port in the United Kingdom, or in any British possession, according as he shipped from one country or the other; and his conveyance thereto, or burial, must also be at the owner's expense. It is only when he is absent, however, from the United Kingdom, or the British possession from which he shipped, that the seaman in case of injury suffered in the ship's service is entitled to such assistance; for upon well-known general principles, every servant is presumed to make his contract with a full knowledge of all the risks of the service upon which he is entering.

A most praiseworthy effort has been made to bring the British seaman in every quarter of the globe completely within the protection of the British laws. There is a system of lists of crews for foreign-going ships upon every voyage, and for home-trade ships once every six months, by which a complete register of British seamen is produced, and a somewhat minute knowledge of each individual and his whereabouts is attained. On every sea where her majesty's flag floats over a vessel of war, on every coast where a British magistrate resides, or a British consular officer officiates, there is opportunity for the injured seaman to complain and obtain justice; and any attempt of the master or other officer of his own ship to interfere with or prevent him complaining is an offence punishable with fine and imprisonment.

It is a misdemeanor for a master to force on shore or wilfully leave behind any seaman or apprentice in or out of her majesty's dominions. It is a misdemeanor to discharge any seaman or apprentice at any place out of her majesty's dominions, or in any British possession, except that from which he may have originally shipped, without the sanction in writing of the shipping master, chief officer of customs, British consular officer, or of two respectable merchants resident at or near the place. It is a misdemeanor to leave behind a seaman or apprentice without at the same time obtaining a certificate from such officer or merchants, stating the fact and the cause indorsed on the ship's articles, unless that was impracticable, and the proof of that lies on the master. In case such discharge however be sanctioned, the wages of the seaman are to be paid on the spot by bill or money. And wherever such discharge is rendered necessary by the transfer of the ship at a place out of her majesty's dominions, unless the crew consent to continue with the vessel, it is obligatory on the master to procure a passage homeward for the seaman, or provide him with employment in some other British ship bound for the shipping port in this country, besides paying their wages, and giving them each a certificate of discharge.

Discharges.—The discharge of seamen at home from foreign-going ships is to be before a shipping master. The wages are to be paid in his presence, subject to his cognisance of the rights of both parties under the agreement. No deductions can be made unless the book in which they were entered at the time of forfeiture be produced to the shipping master twenty-four hours before the time of payment. The time of payment fixed by the statute in the case of home-trade ships, is within two days after the termination of the agreement, or otherwise at the time of discharge; and in all other cases, except those where the seaman is remunerated by shares in the adventure, within three days after delivery of the cargo, or within five days after the seaman's discharge, whichever first happens. A mutual release is given by the master and seaman, countersigned and attested by the shipping master; it operates a mutual discharge of all demands in respect of the voyage or engagement, and is the only evidence of the release or satisfaction of any claim required to be thus settled.

Wills.—The wills of seamen have always hitherto been deemed good and effectual although made without writing. No change in this respect has been made that is imperative. But as the Board of Trade are put in possession of the effects of all seamen dying abroad or at sea, that Board may in virtue of the statute refuse to give effect to any will which is not in writing, and signed or acknowledged by the testator in the presence of the master, or first or only mate of the ship, and attested by such master or mate; or if made on shore, unless signed or acknowledged by the testator in the presence of, and attested by two witnesses, one of whom must be a shipping master, minister, officiating minister, or curate of the place; or if there be no such persons, a justice of the peace, British consular officer, or officer of customs. Upon refusal to give effect to any will not so written and executed, the goods and money of the deceased will be distributed among the next of kin under the statutes of distribution.

As to BARRATRY by master or seamen, or both, see the article under that head.

4.—*Of the Carriage of Goods and Passengers in Merchant Ships, the Rights and Duties, &c. of Freighters and Passengers, of Owners and their Servants. The Contract of Affreightment.*—The contracts under which goods are conveyed in a ship are, as has been already stated, of two kinds, the contract by charter-party, and the contract for their conveyance by a general ship. The former is "a contract by which an entire ship, or some principal part thereof, is let to a merchant for the conveyance of goods on a determined voyage to one or more places." A charter-party is a written instrument, not necessarily under seal, which is executed by the owners or the master, or the owners and the master of the one part, and by the merchant or his agent of the other part. The word charter-party is derived from the two words *charta partita*, "divided charter," because the duplicates of the agreement were formerly written on one piece of paper or parchment and afterwards divided by cutting through some word or figure so as to enable each party to identify the agreement produced by the other. If the charter-party is by deed, and executed by the master, and the owners are not parties to it, they cannot bring a direct action upon the instrument; indeed the owners can never bring an action upon it unless their names appear as the parties executing it. But an action may in all cases be brought against the owners for a breach of their duties generally as ship-owners relating to matters not inconsistent with the terms of the charter-party. The charter-party states the port or ports of destination and the freight to be paid, which may be either a gross sum or so much per ton, or so much for each tub or cask of goods. If the agreement is not to pay a certain sum for the entire ship, or a certain portion of it, but to pay so much per ton, the merchant generally covenants to load a fixed amount or a full cargo. The charter-party generally also states the burden of the ship, but this statement, where there is no fraud, is not binding on the parties. The merchant may load with his own goods or those of others, or he may underlet the ship altogether. The master or owner usually covenants "that the ship shall be tight and staunch, furnished with all necessaries for the intended voyage, ready by a day appointed to receive the cargo, and wait a certain number of days to take it on board. That after lading she shall sail with the first fair wind and opportunity to the destined port (the dangers of the sea excepted), and there deliver the goods to the merchant or his assigns in the same condition they were received on board; and further that during the course of the voyage the ship shall be kept tight and staunch, and furnished with sufficient men and other necessaries to the best of the owner's endeavours." The merchant usually covenants to load and unload the ship within a specified time.

The charter-party dates from the day on which it is delivered or signed. The terms generally used may of course be varied so as to meet the intention of the parties. They cannot be altered or suppressed, or others added by any verbal statements, but they may be explained by evidence of the usage of trade in general, or of that particular trade in reference to which the charter-party is made. The charter-party also generally contains two covenants which seem to be wholly inoperative: one, by which the merchant binds himself and the cargo; the other, by which the owner binds the ship and freight in a penal sum, for the performance of their respective covenants. In an action on the charter-party the actual damages proved will determine the amount to be recovered; and they will neither be limited nor extended by the penal sum named; and although by the general maritime law the ship and freight might be made directly available, there are no means for accomplishing that object in this country. As to the cargo, it is always subject to the general law of lien, unless the parties by their contract expressly discharge it.

Under a contract of affreightment doubt often exists as to whether the goods conveyed are in the possession of the party entitled to the payment, and consequently there is doubt as to his having a lien on the goods. The question to be decided is whether the owner has parted with the possession of his ship. If he has entirely surrendered all control over the ship to the merchant who has chartered her, the merchant must be considered for the time as in possession of the ship. The goods on board, therefore, will be in his possession, not in the possession of the actual owner, who accordingly under such circumstances will have no lien on the goods for the payment of the freight. But it must clearly appear from the language of the charter-party taken altogether, and explained by the circumstances of the employment of the ship, that it was intended that such a complete demise of the ship should be made, one of the rules of construction being to interpret such instruments "agreeably to the nature of the contract that a prudent shipowner would make." The right of lien always exists where the freight is to be paid before or on the delivery at their place of destination of the goods, or even, as Lord Tenterden himself decided (2 Barn. and Ald., 603), where there is "nothing to show that the delivery of the goods was to precede the payment of that hire." All these difficulties may be avoided by inserting a clause in the charter-party expressly stating whether it is meant that the owner should have a lien upon the lading for his freight and expenses. The owner does not lose his right of lien by depositing the lading in a public warehouse, provided he gives notice that it is to be detained until his claim for freight is satisfied.

If either party is not ready to perform the contract contained in the charter-party by the time agreed on, he is liable to an action for non-performance of his contract, and the other party may form fresh contracts with third persons.

The charter-party generally contains a clause by virtue of which the freighter is entitled to detain the ship a certain further number of days for the purpose of loading and unloading her, on payment of a fixed sum per day. This payment and the time during which it occurs are both called demurrage: see that article [DEMURRAGE].

When a ship or a principal part of it is not let out by charter-party, the owners contract with several merchants respectively for the conveyance of their goods. A ship so employed is called a general ship. The terms of the contract appear from the instrument called a bill of lading, two or three of which are signed by the master after the ship has been loaded. If any notice or advertisement relative to the destination of the ship has been issued, care should be taken that these are accurate, otherwise the owners may be liable for the consequences of the misstatement. The terms of the bill of lading must be made out according to the direction of the shipper, or, in case a receipt has been given on the delivery of the goods on board, of the holder of the receipt. The form of a bill of lading is stated in a former article. [BILL OF LADING.]

The master on signing the bill of lading should not deliver it except in return for the receipt which he may have given for the goods. By the Bills of Lading Act (18 & 19 Vict. c. 111), every bill of lading in the hands of a consignee or indorsee for valuable consideration, representing goods to have been shipped on board a vessel, shall be conclusive evidence of such shipment as against the master or other person signing the same, notwithstanding that such goods or some part thereof may not have been so shipped, unless such holder of the bill of lading shall have had actual notice at the time of receiving the same, that the goods had not been in fact laden on board; provided that the master or other person so signing may exonerate himself in respect of such misrepresentation, by showing that it was caused without any default on his part, and only by the fraud of the shipper or of the holder, or some person under whom the holder claims. As between the master or owners and the shippers, the bill of lading is in the nature of a receipt, which is only evidence of the matters which it states, and is subject to be contradicted by proof of the real facts. In case of an action for any breach of their implied contract as carriers, against the master or owners, the party who owns the goods mentioned in the bill of lading must be the plaintiff. This will be the consignee of the goods, unless the peculiar circumstances of the case are such as to deprive him of that character. If it is considered necessary to make any provisions relative to demurrage, they are generally inserted in the margin of the bill of lading.

A contract for the conveyance of goods may be rescinded by the act of the parties or by circumstances over which they have no control. If the contract is under seal, it ought, with a view to proceedings in the courts of common law, to be discharged by an instrument of the same nature; but if the facts show an intention in both parties to rescind the contract, a court of equity will interfere in that behalf. Where the goods have been laden and bills of lading signed, the master ought to receive back all the bills of lading or be indemnified against the consequences of having signed them, if the contract of conveyance is to be put an end to: and he has a right, in the absence of any fresh agreement to the contrary, to retain the goods till the freight which he might earn upon them has been paid. If after the contract for conveyance has been entered into, the fulfilment of it becomes unlawful in consequence of some act of the government of the country, such as a declaration of war, a suspension of commercial intercourse, or a prohibition to export, the agreement is dissolved. But nothing short of absolute unlawfulness can excuse the performance of the contract. A contract is not dissolved by the temporary restraint of an embargo, nor, as it seems, of a blockade of the port of departure. But a blockade of the port of destination dissolves the contract, because to sail to a blockaded port with the premeditated intention of breaking the blockade is an offence against the law of nations. If a party has absolutely contracted to furnish a lading for a ship on her arrival at a foreign port, and is prevented from doing so in consequence of any law or regulation merely municipal of the foreign country, this will not excuse the non-performance of his contract: as where the export of the articles contracted to be laden is prohibited, or where intercourse is forbidden in consequence of the prevalence of an infectious disorder. In such cases, and where from any other cause the correspondent of the merchant is unable to furnish a freight, and gives information of that to the master, he cannot, by afterwards remaining at the port the days prescribed, entitle the owners to demurrage.

Passengers.—In all matters that regard the ship, the master has within the scope of his duty an unlimited authority over the passengers as well as over the crew. A passenger may quit the ship, but while he remains on board he is bound in case of necessity to do work that is required for the service of the ship and to fight in her defence. If he thwart the master in the exercise of his authority or otherwise misconduct himself, he may lawfully be put under restraint or imprisoned. If the conduct of a passenger be unbecoming, or if he threaten the master with personal violence, he may be excluded from those parts of the ship which are frequented by the superior passengers, although he has paid such a fare as entitles him to be admitted there. If a passenger feels himself aggrieved by the manner in which he has been treated, he may bring an action against the master, and it will be for the jury, under the direction of the judge, to say whether he has any ground for complaint. In addition to this general right of action, a general statute (18 & 19 Vict. c. 119) has been passed to regulate the conveyance of passengers from places in the United Kingdom to places out of Europe, and not within the Straits of Gibraltar. It regulates the proportion of passengers carried to the tonnage of the ship, provides security for the sea-worthiness, cleanliness, outfit, and proper storing of the ship, for the presence of a surgeon and medicines, for the delivery of a list of passengers to the collector of customs at the port of departure, and attaches penalties to a violation of the regulations which it contains. It also subjects the master to a penalty in case of his improperly landing passengers at any place not contracted for, or wilfully delaying to sail, and provides for the maintenance of the steerage passengers for 48 hours after their arrival at the destined port. The agreement with the passengers must be in writing, and have a scale of provisions attached. Prepayment of the fare by a steerage passenger within the statute is imperative. If a passenger fails to pay his fare, the master or owners have a lien on his luggage for the amount. Nothing is due for the conveyance of an infant born during the voyage. Where there is a contract for the conveyance of men or animals, freight is not due for those which die before the completion of the voyage, unless there be in effect a stipulation that freight is to be paid for the lading of them. The statute provides for the forwarding of all passengers found at any place short of their port of destination, and as this is done at the expense of the owners of the ship that should have conveyed them, all who accept of this kind of assistance forego their right of action against them.

Duties under Contract of Affreightment.—It is the duty of those who have contracted to convey, to do everything and be provided with everything necessary for the safe and expeditious accomplishment of the voyage; and if, through their failure to perform these duties, any damage results to the merchant, they will be answerable for it. At the commencement of the voyage the ship must be sea-worthy, tight, staunch, and sufficient, and properly equipped with all necessary tackle. He who lets the ship is not excused by his ignorance of any deficiency in these respects. The ship must also be provided with a master and crew competent to command and work her, and to guard the cargo on board, and also with a pilot when necessary either from circumstances or from the law of the country. [PILOT.]

It is the duty of the master, unless in case of any usage which relieves him from such duty, to provide things necessary for the lading of the vessel, and to stow away the goods so that they do not injure each other or suffer from the motion or leakage of the ship. The master must procure and keep all documents, papers, clearances, &c. required by the authorities in respect of the ship and cargo; and he must abstain from taking or keeping on board contraband goods or false papers. He must wait during the time appointed for loading the vessel, and, if required, also during that appointed for demurrage. He must pay the charges and duties to which the ship is subject. The statutes 16 & 17 Vict. c. 107; 23 Vict. c. 22; 23 & 24 Vict. c. 110, contain the enactments relative to what is necessary to be done in respect of the custom-house regulations by ships carrying goods from the United Kingdom beyond seas. When all things are prepared, the voyage must be commenced as soon as the weather is favourable. If the ship is to sail under convoy, she must sail first to the rendezvous assigned. Convoy means such ships of war as, in time of war, are appointed by the proper authorities to take charge of trading ships during their voyage to their respective destinations. Before sailing it is the duty of the master to obtain all the sailing orders and other necessary instructions which are issued by the commander of the convoy; and during the voyage to obey these and any others which may afterwards be issued, and to keep company with the convoy. During the time of war it is often rendered imperative upon merchant ships, by acts passed for that purpose, not to sail without the protection of convoy. After the commencement of the voyage, the master is bound, without delays, deviations, or stoppages, to sail direct to the port of destination. But stress of weather, the appearance of enemies or pirates, or the presence of any urgent necessity, will justify him in breaking through this rule; and he ought to do so for the purpose of succouring another ship which he finds in imminent peril or distress.

If the ship is lost or the goods injured during a deviation without any of these grounds of justification, the owner and master will be answerable for the loss to the merchant, even if it does not appear to have been a necessary consequence of the deviation. If the ship during the voyage is so damaged that she is unable to proceed without repairs, the master may detain the cargo, if not of a perishable character, till the repairs are made. If the cargo is of a perishable kind, he ought to tranship for the port of destination, or sell it where she lies if there be no opportunity of transhipment, or that course appear to be obviously injudicious. He may in all cases, where the circumstances require it, exercise a discretion as to transhipping the cargo; as, for instance, when the ship is wrecked or in imminent danger.

Hypothecation of a cargo, like hypothecation of a ship, is "a pledge without immediate change of possession." The party to whom the goods are hypothecated immediately acquires a right to have possession of them if the money advanced is not paid at the time agreed on. This power of the master under circumstances of urgent necessity to sell or hypothecate the goods must be exercised with great circumspection; and the exercise of it can only be justified when it is consistent with what would have been the conduct of a discreet and able man under the circumstances. During the voyage the master is bound to take every possible care of the cargo, and to do all things necessary for its preservation, and he and the owners will be answerable for all damage which might have been avoided by the exercise of skill, attention, and forethought. When the voyage is completed, the master must see that the ship is properly moored, and all things done relative to her which are required by the law or usages of the country. The statutes 16 & 17 Vict. c. 107; 23 Vict. c. 22; 23 & 24 Vict. c. 110, contain the regulations relative to customs to which it is necessary to conform in this country. Upon payment of freight and the production of bills of lading, the cargo must be without delay delivered to the parties entitled to receive it. If the freight due on any goods is not ready to be paid, the master may detain the goods or any part of them.

When the master is compelled, by an act of parliament, to land the goods at any particular wharf, he does not thereby part with the possession of the goods, and consequently does not lose whatever right he may have to detain them. If goods are sold by the custom-house officers before the freight is paid, the master is entitled to receive the first proceeds of the sale in discharge of the freight. In foreign countries, where any accidents have occurred to frustrate or interfere with the objects of the voyage, or any one of the parties to the contract feels himself aggrieved by the conduct of any other, it is customary to draw up a narrative of the circumstances before a public notary. This narrative is called a protest, and in foreign courts is admissible in evidence generally; but in our courts it is not admissible, except as evidence against those who made it.

Non-performance.—Certain circumstances operate as an excuse to the master and owners for non-fulfilment of their contract. "The act of God" is understood to mean those accidents over which man has no control, such as "lightning, earthquake, and tempest." The "perils of the sea," interpreted strictly, apply only to the dangers caused merely by the elements, but these words have received a wider application, and in litigated cases the jury, after hearing evidence as to the usage which prevails among merchants, will determine what interpretation has been intended to be given to them. In the exercise of this discretion, juries have determined that the taking of ships by pirates is a consequence of the perils of the sea; and the verdict has been the same where the loss was caused by collision of two ships without any fault being attributable to those who navigated either of them; and also where the accident was caused wholly by the fault of those on board another ship. But all cases in which the loss happens by natural causes are not to be considered as arising from the perils of the sea. If the ship is placed in a dangerous situation by the carelessness or unskilfulness of the master, and is in consequence lost, this is not a loss from the perils of the sea, although the violence of the elements may have been the immediate cause of it. If a ship is reasonably sufficient for the purposes of the voyage, the master will not be liable for a loss arising from the perils of the sea, because a ship might have been built strong enough to resist them. The "restraint of princes and rulers" is understood to mean a really existing restraint, not one which is anticipated, however reasonably or honestly.

The merchant must use the ship only for lawful purposes, and not do anything for which it may be forfeited or detained, or the owners made liable for penalties. In case of any violation of the agreement, by employment of the ship for purposes other than those contemplated, or failure to perform the terms as to lading, &c., the amount of compensation, in case of dispute, is determined, as the circumstances of the case may require, by a jury. The words primage and average, which appear in the bill of lading, mean, the first, a small sum paid to the master; the second, as there used, certain charges, varying according to the usage of different places, for towing, beaconage, &c.

Freight.—When an agreement for conveyance is expressed in the general form, or when there is no actual agreement, but only one implied by law from the circumstances of the case, there results from it a duty upon the master and owners, first to deliver the goods at the place of destination, whether the ship is hired by the voyage or by the month. It is only by the entire performance of this duty that they can entitle themselves to the payment of freight. The parties may, however, so express the contract that the payment of all or part of the freight may be due before or during the course of the voyage; in such case the word freight is used in a sense which does not properly belong to it; for in strict usage it means only money earned by the conveyance of goods and their delivery at the place of destination. Where a provision is made by the contract for payment of freight at the place of shipment, the question has arisen whether the meaning of the parties was that the sum should be paid at all events on delivery of the goods on board, whatever might afterwards befall them; or whether it was merely to point out the place of payment in case the freight should become due by reason of the arrival of the goods at the port of destination. In all such cases the intention of the parties is a question of construction for the court subject to any usage of the port where it was made, or of the trade with which it is connected. The same observation will apply to cases where money has been advanced by the merchant, and it is disputed whether the money is to be considered as a loan or part payment of the freight.

If the master unnecessarily sell the goods, and so prevent both himself from earning the whole freight, and the merchant from accepting the goods, the merchant is entitled to the entire produce of his goods without any allowance for freight. If the ship has actually never commenced the voyage, the owners are not entitled to any payment whatever, although they may have incurred great expenses in lading her, and though her failure to commence the voyage is not attributable to any neglect or misconduct of theirs. Where the contract of hiring is for a voyage out and home, at the rate of so much per month, &c., during the time the ship is employed, and the contract is entire, no freight is due unless the ship returns home, even though she may have delivered her cargo at the outport. But if the voyages out and home are distinguished in the contract, freight will be earned on the delivery of the cargo at the outport. See further under BILL OF LADING and FREIGHT.

General Average.—If any part of the ship or furniture, or of the goods, is sacrificed for the sake of saving the rest, all parties interested must contribute towards the loss. This contribution is properly called 'Average.' It is sometimes called general average, in opposition to special or particular average, which is the contribution towards any kind of partial damage or loss, or gross average, in opposition to petty average, which is the contribution mentioned in the bill of lading towards the sums paid for beaconage, towage, &c. [AVERAGE.]

The principle of average is recognised in the maritime law of all nations. It was introduced into the civil law from the law of Rhodes ('Dig.' 14, tit. 2, "Lex Rhodia de Jactu;" and the Commentary of Peckius, "In tit. 'Dig. et Cod.,' 'Ad Rem Nauticam pertinentes.'") In order to constitute such a loss as is the subject of average, it must be incurred by design: the masts must be cut away, or the goods thrown overboard; and this must be done for the sake of saving the rest, as in the case of throwing goods overboard to keep the vessel from sinking or striking on a rock, or to lighten her that she may escape from an enemy, or of cutting away a mast or a cable to escape the perils of a storm. The necessary consequences of these acts are also the subjects of average; as where, in order to throw some goods overboard, others or some parts of the ship are damaged; or where it becomes necessary, in order to avoid the danger or repair the injuries caused by a storm or the enemy, to take goods out of the ship, and they are in consequence lost. The expenses also incurred in these operations are equally the subject of average. But the injuries incurred by a ship during an engagement with the enemy, or from the elements in consequence of measures taken to escape from an enemy, are not of such a nature as to fall within the definition. If goods are laden on deck, no average is recoverable in respect of the loss occasioned by throwing them overboard, unless by the usage of trade such goods are usually so laden. If a ship is voluntarily stranded for the purpose of saving her and the goods, and afterwards gets off safely, the expenses incurred by the stranding are the subject of general contribution; but if the ship be wrecked in consequence of the voluntary stranding, there is a difference of opinion whether the wrecking be voluntary, and therefore such a loss as calls for a general contribution. If, in consequence of such an injury done to a ship as would be the subject of average, she is compelled to go into port to repair, the necessary expenses incurred in refitting her, so as to enable her to prosecute her voyage, and the amount of wages, port dues, and provisions expended to accomplish that object, are also the subject of average; and, if the master is unable to obtain the money necessary by any other means than by the sale of a part of the cargo, the loss caused to the merchant upon such sale is also the subject of average. If, in consequence of the sacrifice made, the ship escape the danger which immediately threatens her, but is afterwards wrecked or captured, and the remaining goods, or part of them, are saved or recaptured, these are bound to contribute average towards the loss in the first instance incurred, in proportion to their net value in the hands of the merchant after all expenses of salvage, &c., have been paid.

The things upon which average is payable are, the ship, boats, furniture, &c., but not provisions or ammunition; also all merchandise, to whomsoever belonging, which is on board for the purposes of traffic, but not the covering, apparel, jewels, &c., of parties on board for their own private use. The freight due at the end of the voyage is also subject to average. The goods are to be valued at the price for which they would have sold at the place of destination. If the ship, by reason of what happened when the average was incurred, return to her port of lading, and the average is there settled, the goods are to be valued at the invoice price. The losses incurred by the ship and furniture, &c., are calculated at two-thirds of the price of the new articles rendered necessary to be purchased. The usages of other countries as to all matters connected with average differ in some respects both from those of each other and those of this country. Where the average has been adjusted according to the established law and usage of the country in which the adjustment was made, it is binding upon all the parties to it, unless there be some special contract between them which provides otherwise.

Salvage.—Salvage is that reasonable compensation which persons are entitled to receive who, in the absence of any obligation making it their legal duty, voluntarily save a ship or her cargo from loss by peril of the sea, which may be called civil salvage, or recover them after capture, which may be called hostile salvage. By the law of England, no fixed amount of salvage is laid down as applicable to all cases. What is reasonable can only be determined by a reference to the circumstances. Sir J. Nichol (3 Hag., 'Ad. Rep.,' 117) defines the ingredients in estimating a civil salvage service to be, "1st, enterprise in the salvors in going out in tempestuous weather to assist a vessel in distress, risking their own lives to save their fellow-creatures, and to rescue the property of their fellow-subjects; 2nd, the degree of danger and distress from which the property is rescued, whether it was in imminent peril, and almost certainly lost if not at the time rescued and preserved; 3rd, the degree of labour and skill which the salvors incur and display, and the time occupied; lastly, the value."

Unless in cases where the services have been trifling, the salvage is generally not less than a third and not more than one-half of the property saved; at the same time there is no rule now of specific proportions. If the parties cannot agree as to the amount, the salvors may retain the property until compensation is made; or they may bring an action, or commence a suit in the Admiralty Court, against the proprietors for the amount. In case the property is retained, the proprietors may, upon tender of what they think sufficient, demand it, and, if it is refused, bring an action to recover it, in which action the jury will determine as to the amount due. The costs of the action will be paid by the salvor or the proprietors, according as the amount tendered is or is not determined to be sufficient. The Court of Admiralty has jurisdiction originally in those cases where the salvage has been effected at sea, or within high and low water mark. A passenger is not entitled to salvage for his assistance during the time he is unable to quit the ship. But, if he remain voluntarily on board, he may recover salvage for the assistance which he has given. On one occasion, where a passenger under such circumstances, after the desertion of the master and part of the seamen, assumed the command with the consent of the mate and the remainder, and brought the ship safe into port, he obtained a large sum as salvage. A distinct contract for assistance will do away with any claims for salvage on behalf of the parties who render it. Though a king's ship is bound to assist a merchant ship in distress, it still has a claim for recompense, but cannot prosecute it without the leave of the Board of Admiralty. In awarding salvage, no claims are allowed which are founded on merely prerogative rights, as those of the lord-high-admiral, flag-officers, magistrates, &c.: those claims only are allowed which are made in respect of assistance rendered. The saving of human life cannot of itself be the subject of a claim for salvage, except upon the shore of any sea or tidal water of the United Kingdom (17 & 18 Vict. c. 104); but if it is connected with the preservation of property, that is a circumstance which may affect the amount of salvage. If freight is in progress of being earned, and afterwards does become due, salvage is payable in respect of freight also. When proceedings for salvage have been commenced in the Admiralty Court, the defendants may tender by act of the court any sum which they consider sufficient, and the court will then enter upon an inquiry, and determine what is right between the parties. If the sum tendered has been sufficient, the court may hold the salvors liable to the expenses of the proceeding. With regard to wreck, ships in distress, and for salvage purposes, the Merchant Shipping Act creates receivers of wreck to be appointed at different places on the shores of the United Kingdom for the express purpose of doing all things possible towards the saving of ships in distress, for the recovery and preservation of wreck, and for facilitating the agreement of salvage disputes when the amount is under 200*l.* The receiver may distribute the amount and take receipts if the parties agree; but if not, they may carry their differences before the nearest two justices of the peace, whose decision is final on all sums not exceeding 50*l.* Above that amount, there is an appeal to the Court of Admiralty. If the sum exceed 200*l.*, they may institute the suit in that court in the first instance. Great powers are reposed in the receiver of wreck for collecting assistance, and impressing horses and carts into the service for rendering aid to vessels in distress, for repelling all attempts at violently boarding the ship with felonious purposes, and for the recovery of concealed wreck. Provision is made for cases where no owner of the property appears. Perishable goods may be sold. No lord of a manor claiming a title to wreck can appropriate it until an account in writing of the property, and of the place where it was found and it has been since deposited, has been sent to the nearest custom-house, or if it exceed in value 20*l.* to the secretary at Lloyd's, and a year has elapsed after the delivery of the account. A variety of analogous provisions are enacted relative to goods, parts of ship's furniture, &c., which are found or recovered, whether they may have belonged to ships in distress or not. The statute which relates to the Cinque-Ports is 1 & 2 Geo. IV. c. 76.

In case of capture, by the ancient maritime law the ship and goods became the absolute property of the captor. The old practice in this country was, when ships were in pay of the king, to divide in certain proportions, which varied at different times, the value of the capture between the king, the owners, and the captors. Where the capture was made by ships not in the king's pay, he received no share, but a small proportion was paid to the admiral. In the reign of George II. provision was for the first time made by various statutes for the restoration of the recaptured ship and cargo to the owners, and the rates of salvage were fixed, varying according to the length of time that had elapsed since the capture. In the reign of George III. these rates were done away with, and by various acts the rate of salvage was fixed at one-eighth of the value in the case of king's ships, and one-sixth for private ships; where the re-capture was effected by the joint operation of king's and private ships, the Court of Admiralty were to order such salvage as was reasonable. Convoying ships are entitled to salvage for the recapture of ships which accompanied them. A ship, which has once been used as a ship of war, is not subject to be restored if afterwards recaptured. If a ship is deserted by the enemy after capture and subsequently taken possession of, this is not a recapture, but those who take possession are entitled to recompense as in an ordinary case of salvage. If after the recapture the ship is again taken and condemned, the right of salvage is extinguished. Where the ship of a power in alliance with Great Britain is taken by the common enemy and afterwards recaptured by a British ship, the rule for restitution on payment of salvage is the same as in the case of the capture of a British ship; provided the allied power chooses to adopt that rule in reciprocal cases. If it does not, the same rule which is acted upon in the courts of the allied power is adopted in the British courts. If the ship of a neutral nation be taken as prize by an enemy of Great Britain and be retaken by British subjects, it is restored to the owners without salvage, unless there is reason to suppose that under the circumstances the ship would have been condemned in the courts of the capturing nation. Where it appears that such would have been the case, the British subjects are entitled to salvage. Ships and merchandise taken from pirates are subject, by 6 Geo. IV., c. 49, to a payment of one-eighth of the value. [PRIZE.]

(Maclachlan, *On the Law of Merchant Shipping;* Abbott, *On Shipping,* by Serj. Shee; Maude and Pollock, *Compendium of the Law of Merchant Ships.*)

SHIPWRECKS. That wrecks are numerous, is a fact well-known to a seafaring nation like ours; that they must necessarily be considerable in number, regard being had to the perils of the deep, will of course be admitted; but that nothing can be done to lessen their frequency, would be a hopeless theory of which we ought to be ashamed. Supposing, for the sake of fixing the ideas, that some wrecks are occasioned by a want of scientific knowledge of winds, waves, currents, whirlpools, shoals, reefs, and sunken rocks, on the part of meteorologists and hydrographers; that others are caused by the incompetency of captains and mates; that others again result from the insubordination, carelessness, ignorance, or obstinate fatalism of seamen; that a fourth group are due to the deficiency of lighthouses, beacons, and buoys; and that the remainder arise from want of ready assistance to ships which, though placed in peril on shoals or near rocks, might yet be saved if aid were at hand on the beach or the cliff —who shall say that these evils are incurable? who can put a limit to the improvements which might be wrought?

A dismal story, indeed, does the "Wreck-chart of the British Islands" tell, as published annually by the Admiralty, and afterwards in the 'Life-Boat Journal.' It may be designated a truly distressing map. Every wreck on our coasts has its little black mark; and the aggregate of such black marks reveals the number of wrecks in one year. Knowing that a black spot ● indicates a vessel wrecked, and that + indicates a vessel so seriously damaged as to need to discharge cargo, we look eagerly for the relative numbers of these little spots and stars; and it is saddening to see how numerous are the fatal black signs. At some places the wrecks are numerous because the coast is dangerous; at others, because the congregating of ships is very great. These charts refer only to our own coasts—the coasts of the most busy maritime islands in the world; where, if there be liability of disaster through the vast congregation of shipping, there ought, on the other hand, to be a supply of invention and good sense sufficient to check, in some degree, such disasters. In examining the details of the chart, it will be seen that the line of coast between Dungeness and the Pentland Frith is the most fatal, and that the mouth of the Tyne takes the unenvied precedence of all other places, in the number of black dots and stars opposite to its name; next come the mouth of the Tees and the mouth of the Wear. These three rivers may be taken as the representatives of the district whence three million tons of coal are brought by sea to London yearly, employing the services of several thousand collier ships, which sail to and fro, and add to the otherwise busy commercial trade of the Northumbrian and Durham ports. The mouth of the Humber, the Suffolk coast between Yarmouth and Southwold, the intricate sandy shoals off the mouth of the Thames, the Goodwin Sands, the Scilly Islands, Barnstaple Bay, and Liverpool, are the portions of the English coast which present, in the next degree, the most numerous indications of ship-losses. The Welsh coast is thickly strewn, especially Glamorgan, Pembroke, and Anglesea, Scotland, except in and near the Frith of Forth, presents no large numbers; the western coast is, indeed, remarkably free, due probably to the less exposure to the winds which tend to drive ships ashore on our eastern seaboard. Ireland presents a tolerably equable distribution along the east and south coasts: less on the northern and western.

Many inquiries into the causes of shipwreck have been instituted; and especially one by a committee of the House of Commons. One of the results has been the construction of harbours of refuge, which have not hitherto been very successful. One frequent cause of wreck is collision, arising from bad look out or neglecting to show light. Another cause was the occasional incompetence of the master in merchant vessels. To remedy this, Mr. Cardwell, in 1854, brought in and carried a bill "To Amend and Consolidate the Acts relating to Merchant Shipping;" it constitutes the act 17 & 18 Vict. c. 104, and received the royal assent August 10, 1854. The statute is of great length, and relates to eleven different topics, bearing upon the well-being of sailors and their ships:—the relation of the Board of Trade to the commercial marine; the ownership, measurement, and register of British merchant ships; the qualifications of masters and seamen; the precautions for safety on ship-board; the arrangements concerning pilots; the management and tolls of lighthouses; the constitution of the Mercantile Marine Fund; the laws relating to wrecks, casualties, and salvage; the liabilities of ship-owners; legal course of procedure in the event of misdemeanor; and miscellaneous details. Inspectors of merchant ships, and investigators in respect to wrecks and accidents, are appointed by the Board of Trade; new examinations for masters and mates are organised, separating foreign-going ships from home-trade passenger ships; the Board is empowered to suspend certificates to masters and mates, in case of misconduct or inefficiency; naval courts are instituted abroad or on the high seas, in correspondence with the Board, to inquire into cases of wreck or abandonment of ships; the number and size of the boats to accompany all trading ships are denoted; every ship carrying more than ten passengers must be provided with a life-boat, or an ordinary boat rendered buoyant, and with two life-buoys—the boat and buoys being always kept ready for use; lights and fog-signals are to be used, such as may be suggested by the Admiralty; iron steamers must have water-tight compartments, and safety-valves beyond the control of the engineer; sea-going ships must be provided with fire-engines and hose, signal-guns, and ammunition for firing signals of distress.

Besides the provision for preventing wreck, the Act contains many clauses, applying to cases in which wreck may unhappily have occurred. As these arrangements are somewhat peculiar, it may be well to notice them a little closely. All matters relating to wreck are placed under the general superintendence of the Board of Trade, by whom "receivers of wreck" are appointed. These receivers have the chief command and authority over all persons present at any wreck, or similar casualty, and power to issue such directions as may seem expedient for the preservation of life and property, or for the prevention of plunder and disorder. Whenever a ship is stranded, or otherwise in distress on British shores, bystanders are encouraged to render assistance, by having a pecuniary interest in the preservation of life or property. If services so rendered shall be instrumental towards the object in view, the persons shall have a claim on the owner of the ship for a "reasonable amount of salvage." Numerous directions are given for ascertaining what would be a "reasonable amount" in each case; for enforcing the claim of the salvor against the distrainor; for disposing of an unclaimed wreck; and for adding to the salvor's reward out of the Mercantile Marine Fund, in cases where life has been preserved, and where the wrecked ship is insufficient in value to pay the salvage awarded. The Mercantile Marine Fund here adverted to is made up in a curious way: it consists of certain fees received by the Board of Trade for examinations and registries connected with merchant-ships; lighthouse dues accruing by virtue of certain sections of the Act; rates accruing from lastage and ballastage in the Thames; and fees derived through the receivers of wreck. The fund, kept by her Majesty's Paymaster-General, is employed in payment of the salaries of examiners, surveyors, receivers, &c.; expenses in regard to lighthouses, buoys, beacons, lastage, ballastage, life-boats, &c.; and rewards to persons who assist in saving wrecked ships, or crews, or passengers.

Wrecks, however, will still occur on our coasts, and the necessity arises for affording assistance. By the efforts of the National Life-Boat Institution, which has received the support of the government, life-boats have been placed at most of the dangerous parts of our coast. [LIFE-BOATS.] But there are times when other aid is needed; when a ship is in distress so near the shore as to be within reach of a rope, if means were at hand to throw it—while, perhaps, no boats are near the spot fitted to render the required service. What are the crews to do? Sailors, unfortunately for themselves, are in too few cases swimmers; and even a swimmer has a poor chance for his life in such weather and such a sea as usually accompany these strandings of ships. The men generally cling to their vessel as long as her timbers will hold together, rather than strike out and endeavour to swim to shore. In such case their safety mainly depends on the establishment of some communication with the shore. Such communication was the object of Captain Manby's attention, and his name is intimately associated with the history of this part of the subject. He had, in 1783, thrown a line, by means of a small mortar, over Downham Church, in Norfolk; and it struck him that he might, by the same means, throw a line over a stranded vessel. During many subsequent years he made repeated experiments; his main difficulty consisted in securing the shot to the rope; iron chains were liable to break on the discharge; but at length he found that stout strips of closely-plaited raw hide would answer the purpose. The rocket apparatus is now thoroughly effective, and many thousand lives have been saved by means of the ropes thrown out to stranded ships, through the agency of mortar-rockets. There are upwards of 200 places on the shores of the United Kingdom, where such apparatus is kept, mostly under the charge of the coast guard, who, from the peculiar nature of their other duties, are well adapted for this kind of service.

SHIRE, from the Saxon *schyran*, to divide (whence also *to shear*), is the name of districts into which the whole of Great Britain is divided. The word shire is in most cases equivalent to *county*, a name often substituted for it in Great Britain, and always in Ireland. The origin of this distribution of the country cannot probably now be ascertained. It has been customary to attribute it to Alfred, upon the authority of a passage in Ingulphus, the monk of Croyland, who wrote about a century and a half after the reign of that king. Asser, however, the biographer of Alfred, does not mention this most important fact, and the unsupported statement of Ingulphus is of little value. In truth, shires were certainly known before Alfred's time. Sir Francis Palgrave shows them to be identical, in many cases, with Saxon states; thus Kent, Sussex, Essex, Norfolk, Suffolk, Middlesex, and Surrey, were ancient kingdoms: Lincolnshire, under the name of Lindesse, was an independent state, and Worcestershire (*Huiccas*) was the jurisdiction of the bishop of Worcester. Shires of another class were formed out of larger divisions, either for the sake of more easy management when the population of the particular district had increased, or for the sake of giving territory to an earl. Yorkshire was part of the kingdom of Deira, and Derbyshire of Mercia. Lancashire was made a county subsequently to the Conquest. On the other hand, some shires have merged in others; Winchelcombeshire is a part of Gloucestershire; and in the Act for abolishing the palatine jurisdiction of Durham (6 & 7 Will. IV., c. 19) no less than five shires are mentioned, namely, Craikshire, Bedlingtonshire, Norhamshire, Allertonshire, and Islandshire; which had long ceased to possess, if indeed they ever enjoyed, separate jurisdictions.

The uses of the division into shires may be learnt by an enumeration of the principal officers in each:—1, the lord lieutenant, to whom is entrusted its military array [LORD LIEUTENANT]; 2, the custos rotulorum, or keeper of the rolls or archives of the county; this officer is appointed by letters-patent under the great seal, and is now always identical with the lord-lieutenant, except in counties of cities, where the high steward is usually custos rotulorum; 3, the sheriff, or, as he is often called, the high sheriff [SHERIFF]; 4, the receiver-general of taxes, who is appointed by the crown, and accounts to it for the taxes levied within his district; 5, the coroner [CORONER]; 6, the justices of the peace, whose commission extends only to their own county, and who, assembled in sessions, have jurisdiction over many offences, and control over the county funds [SESSIONS]; 7, the under-sheriff, who is appointed by and performs nearly all the duties of sheriff; and 8, the clerk of the peace, an officer (almost always an attorney) appointed by the justices in quarter-sessions, whose duty it is to file and produce recognisances, returning them, when forfeited, to the sheriff to be levied [RECOGNISANCE]: he likewise prepares or files indictments to be tried at the sessions or assizes, and in general acts as the officer of the justices in quarter-sessions.

County-rates are assessments made by the justices in quarter-sessions assembled, according to estimates laid before them. The principal objects of these rates are: the building and repair of bridges, jails, shire-halls, and courts of justice, and of late years lunatic asylums; the repair of roads; the payment of the salaries of the coroner, clerk of the peace, high and special constables, jailers, &c.; the expense attending the apprehension, conveyance, and prosecution of persons accused of crime; and under this head is included the remuneration to witnesses for their loss of time and expenses; the maintenance of prisoners, and their transportation. The rates are levied by collectors, and enforced by the sheriff.

The judicial tribunals in each county are the assize court [ASSIZES]; the old schyremote or county-court held for the election of knights of the shire, and the hundred courts, and courts-leet. [COURTS.] These hundred courts and courts-leet have long been almost entirely obsolete, and the county court statutes accordingly contain provisions for their surrender to the crown.

The principal subdivision in a county is the hundred, a district which in its origin bore relation rather to the population than to any uniform geographical limits. Mr. Hallam considers it to have been a district inhabited by 100 free families, and that a different system prevailed in the northern from that of the southern counties; in proof of which he contrasts Sussex, which contains 65 hundreds, and Dorsetshire, which contains 43, with Yorkshire, which contains only 26, and Lancashire, only 6. In the counties north of the Trent, this subdivision is often called a wapentake. That the division into hundreds was known among the Germans, even in the time of the Roman invasion, is argued from two passages in Tacitus ('De Mor. Germ.,') "ex omni juventute delectos ante aciem locant—Definitur et numerus; *centeni* ex singulis pagis sunt." And again, "Centeni singulis (principibus) adsunt ex plebe comites, consilium simul et auctoritas." "Nihil nisi armati agunt;" and hence Spelman infers the identity of the *wapentách*, or military array (taking of weapons) and the hundred court. Sir Francis Palgrave says that the burgh was only the enclosed and fortified resort, the stockade of the inhabitants of the hundred. The subdivision of the hundred was the tithing, composed, as it is alleged, of ten free families, and having for an officer the tithing-man, a head constable.

Whether in the barbarous times to which it is attributed, so elaborate a system as we have sketched could have prevailed, is at least most doubtful; but the theory is that somewhere about the time of Edgar (A.D. 950), the county was divided into tithings, of which 12 made a hundred—for the Saxon hundred meant 120, and hence perhaps the frequent use of the number 12 in our legal processes. These hundreds were presided over by their decanus, or headborough, or hundred-man, and were represented in the shiremote; and this aggregate body, the shire, presided over by its earl and bishop or sheriff, conducted its own internal affairs.

There are three counties-palatine, the earl of which had within his shire all the fiscal and judicial powers of the crown:—Chester, created by William the Conqueror; the duchy of Lancaster, created by Edward III.—these two have been long annexed to the crown; and Durham, formerly governed by the bishop, but annexed to the crown in 1836. In this year a part of the see of Ely, which had been a royal franchise, was annexed to the crown, as Hexhamshire in Northumberland had been in the reign of Elizabeth. [PALATINE COUNTIES.]

SHODDY MANUFACTURE. This has recently become a large and important branch of industry in the West Riding of Yorkshire. *Shoddy* and *mungo* are the strange names given to two varieties of rag-wool; the one being obtained from old blankets, carpets, flannel, and worsted stockings; and the other from tailors' cuttings and worn-out woollen garments. In both cases, the pieces are torn up fibre from fibre, constituting a kind of dirty short-stapled wool. There is a third variety called *extract*, obtained from "union" or "mixed" goods, in which cotton is woven up with wool; rags of this kind are exposed to the action of strong chemical agents, which completely dissolve away the cotton, and leave the wool behind.

So far back as half a century ago, cloth manufacturers began to mix a little rag-wool with new wool in the making of cheap cloth; but it is only in recent years that a large and distinct branch of industry has resulted therefrom. At the present day, Batley and Dewsbury are the centres of the trade, giving employment to many thousand persons in several mills—in producing shoddy and mungo from rags, in sorting and preparing rag-wool imported from abroad, or in spinning the old with the new wool into yarn for weaving into cloth. Besides the two towns here named, the manufacture is distributed throughout the whole of the surrounding district—in Ossett, Mirfield, Morley, Earlsheaton, Heckmondwike, Gomersal, Elland, Stainland, and other places scarcely known even by name out of Yorkshire, but gradually rising from mere villages to the dignity of towns. The trade is a very dirty one. The rags have gone through a long period of service, and are unavoidably soiled and stained in various ways. There are sorters, whose business it is to classify the rags into as many kinds and colours as possible, in order that manufacturers may be able to select the varieties which best suit their purposes. There are also cutters, whose employment consists in cutting off knots and seams, which would otherwise interfere with the operations. The disentanglement of the rags into rag-wool is effected chiefly by a machine called a *swift*. This consists of a revolving cylinder, set with iron-toothed plates; the rags are fed in at one point, and are torn into fibres by the action of the teeth. Some of these machines contain 14,000 teeth, perform 700 revolutions per minute, and are employed in grinding up good woollen rags into mungo; others, with fewer teeth and a slower motion, tear up old worsted rags into shoddy. Each machine produces on an average about 1000 lbs. of rag-wool per day. In the township of Batley alone, it is estimated that there are now from 12 to 14 million pounds produced annually; about an equal amount in various places within four miles of that town; and again an equal amount in places beyond that limit—in round numbers, 50 million pounds of woollen and worsted rags are disentangled into 40 million pounds of mungo and shoddy. Of the whole quantity, about one-third is mungo, of an average worth of 6*d*. per pound; and two-thirds shoddy, worth 4*d*. This amounts to the large sum of nearly 800,000*l*.—a value wholly superadded to that which relates to new wool. A great portion of this is absolute saving to the community: for woollen rags possess only a very small per-centage of this value, when applied to other manufacturing uses.

Mungo and shoddy are not used alone in making woollen goods. New wool is added to them, to give them the felting property and strength of fibre. The very commonest goods may have eight or ten times as much rag-wool as new wool; in medium goods the ratio may be nearly equal; in a higher class of goods there may be eight or ten times as much new wool as rag-wool. It is all a matter of price. One cause for the (apparent) cheapness of woollen goods within the last few years is the large admixture of mungo and shoddy. None but a skilled person can detect this admixture; and in some cloths, indeed, mungo is combined so judiciously with new wool as to produce a really strong material. Mungo made from the best woollen cuttings is, in fact, better than new wool of low quality; and cheapness is here something more than a name. The kinds of cloth chiefly produced, having mungo or shoddy as part of their substance, are numerous, and receive designations conveying very little information except to those engaged in the trade; such as tweeds, flushings, paddings, duffels, friezes, witneys, mohairs, pilots, petershams, strouds, savelists, reversibles, linings, sealskins, doeskins, cheviots, &c. The most extensive branch of the manufacture is that of pilots, a cloth employed in making the heavy substantial "pilot coats" used by sea-faring men. These, like the rest, may have much or little shoddy in them, according to the price to be charged.

The processes need not be described here. They partake of the same general character as those treated under Woollen and Worsted Manufacture. (Jubb, 'History of the Shoddy Trade,' 1860.)

SHOE TRADE. Under Boot and Shoe Manufacture, some of the mechanical features of this branch of industry were noticed. In the present article we shall treat briefly of the relation between the different kinds of workpeople, and of the changes recently effected through the introduction of sewing-machines.

A shoemaker, in the old statutes, is called a cordwainer, apparently a corruption of the French *cordonnier*, which means a worker of Cordova leather. The companies of shoemakers in our ancient towns were incorporated under this name; and where some of these companies still exist, they go by the same name. As a legal term cordwainer is still common. The law of England formerly took cognisance not only of the quality of the leather which the shoemaker wrought into his goods, but of the number of stitches that he furnished.

The trade, as now followed in London and other principal places, is subdivided into about twenty branches. The following may be set down as the chief: the *shoeman*, or maker of the sole part of the shoe; the *bootman*, or maker of the sole part of the boot; and the *boot-closer*, or joiner together of the leg, vamp, &c. The labour of these is especially directed to what is called the *men's line;* whilst others make the ladies' shoe or boot. There are many women, too, who get a livelihood by closing the shoe; while others again practise the various sorts of binding. In the manufacture of a boot, the clicker or cutter having designed and cut the leather of the vamps, legs, &c., to the measure of the customer or the size wanted, the materials go to the closer. Much of the boot-closer's art, as now perfected, is of a very delicate nature, especially in the putting together or closing of all the parts of the top-boot, and the fancy-wrought and coloured Wellington; the common Wellington being the easier portion of his occupation. The bootman does for the boot what the shoeman does for the shoe; he makes or attaches the sole. The labour of this person, however, is much better paid than that of the shoeman; because it has a higher character, and considerably more time is required to complete the article. The best shoemen usually at the first opportunity take to be bootmen. The making of the woman's common or welted shoe resembles that of the man's; and where it differs it is unnecessary here to explain. The man's and woman's single-sole shoes or pumps are also proceeded with in the same manner.

Formerly it was the general practice for the journeyman to work in the shop with his employer; two, three, six, or more, all working together. The journeymen then had sometimes, as now, so much per pair; but he was also paid by the day or week, or was even engaged as a quarterly or half-yearly servant. In every case he had his coals and candles in winter, and in all seasons his finding or grindery free, that is, his hemp, wax, paste, bristles, &c. Wages then were very low; but the work was of an inferior description, and the habits of the time very plain and simple. Towards the end of the last century, the shoemaker's position improved. He gave up working in the shop of his master, or in garrets with several other men. If married, he followed his employment in his own home. If unmarried, he joined himself in a sort of partnership with another workman in a like condition, and taking a furnished lodging, felt more at ease than under the former system of constraint. This still is the practice among the better-paid classes of the trade.

In Boot and Shoe Manufacture, the recent importations of boots, shoes, goloshes, and boot-fronts from foreign countries are noticed. The *exports* from the United Kingdom are not so easily determined, seeing that boots and shoes are in this instance included under the general designation of leather "wrought and unwrought," exclusive however of "saddlery." The return under this head for 1860 was 6,473,826 lbs., having a declared value of 1,407,557*l*. It is computed that about two-thirds of the above quantities consist of boots and shoes, which are exported chiefly to Australia and the other colonies. Mr. M'Culloch, in the latest edition of his 'Commercial Dictionary,' expresses an opinion that the boots and shoes now made annually in the United Kingdom have an aggregate value of 10,000,000*l*.; of which he sets down about one-half for wages, and the other half for materials and profit.

In the article just cited, it was stated that, in 1859, a struggle had arisen between the masters and men concerning the employment of sewing-machines. The masters have now (1861) gained their point, as they are always likely to do where labour-saving contrivances are in question. According to information given in an article by Mr. Charles Knight, in the 'Companion to the Almanac' for 1861, the workmen are gradually yielding, seeing that opposition is of no avail. It was supposed in 1851 that no less than 30,000 persons were in various ways employed by the Northampton boot and shoe-makers alone; and since that year the trade has extended greatly, both at Northampton and Stafford, and in various villages surrounding those two towns. In the large factories, the upper leathers are now to a considerable extent put together by the aid of the sewing-machine; the machines belong to the employers, and there are often fifty or sixty of them in one room. The women employed at the machines earn much more than by hand-sewing; but of course not so many of them are needed. Some of the manufacturers are of opinion that the machines are not suited for men's strong shoes, on account of a difficulty in using waxed thread; but others believe that the machines will gradually impart a wholly new aspect to the trade. The "Northamptonshire Boot and Shoemakers' Mutual Protection Society" was unable to stem the current; and the machines are now employed, not only in the large factories, but by the workpeople themselves. "A dealer in the machines informed me," says Mr. Knight, "that a few provident shoemakers were purchasing the machine for the domestic employment of their families, by which one female of their household would be able to earn more than was formerly earned by the wife and two or three daughters. The advantage would not rest here. The wife would be at liberty, by working a few hours a day at the machine, to have leisure for her domestic duties; and would thus obviate the reproach attached to too many shoemakers' wives, that the dirty home, the slatternly habits, and the neglected children, drive the husband to the public-house. The machines cost from 12*l*. to 25*l*. I saw one which the dealer in machines was about to sell to a steady workman, upon his paying the cost by instalments." The apparatus will be found briefly described under Embroidery and Sewing Machines.

The Americans carry on the shoe-manufacture on a scale not equalled by anything known in this country. A large steam-factory for the purpose has been established at Haverhill, in Massachusetts. In the basement story are machines for cutting, rolling, and shaping the leather for shoe-soles. In the next story the upper leathers are lasted, and the outer soles tacked on. In another range of rooms are the pegging machines; long strips of wood, of the required width, are coiled up, and put into each machine; the machine uncoils the strip, cuts it up bit by bit, makes holes in the shoe, and drives a bit as a peg into each hole; this is effected at the rate of fourteen pegs per second. In other rooms are stitching machines worked by steam.

SHOOTING STARS. [Meteors.]

SHORT-HAND. [Stenography.]

SHORT-SIGHTEDNESS. [Sight, Defects of; Spectacles.]

SHOT are the balls (generally solid) of iron which are discharged from guns, howitzers, or carronades. Those which are used for the first of these kinds of artillery vary in diameter from 1·955 inches, which is that of a one-pound ball, to 7·95 inches, which is the diameter of a 68-pound ball. Shot for howitzers vary in diameter with the nature of that arm, from 4·476 inches, which is the diameter of a 12-pounder howitzer, to 9·88 inches. Carronades, which are now never used, discharged balls weighing from 6 lbs. to 68 lbs., which were of course equal in diameter to those which belong to guns of equal calibre. Hollow shot have latterly been introduced into the service, principally for the navy. The guns for throwing hollow shot are 8- and 10-inch, and are sometimes called Paixhans, from the inventor; though not so light as the howitzers of those calibres, they are lighter than solid-shot guns. They can be used for throwing both shells and hollow shot with small charges. Hollow shot, or unloaded shell, as they are in fact, have this advantage, that though their diameters are large, their weights being small, a small charge gives a high initial velocity, rendering them very effective for short or ordinary ranges, while from their large size they are capable of producing most destructive effects, more especially on shipping. The shot for Rifled Ordnance are described under that head.

SHOT MANUFACTURE. [Lead.]

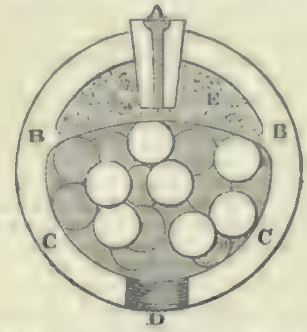
SHRAPNEL SHELLS, so called from the inventor, Major Shrapnel, R. A., are a most destructive description of projectile; they are principally used against skirmishers and scattered bodies of troops beyond the range of common case, 300 yards, or of grape shot, about 600 yards.

A Shrapnel shell or spherical case shot, consists of a thin shell of cast iron, containing a number of musket balls and a small charge of powder just sufficient to burst it, and free the balls; a Fuze, by which the charge is ignited and the shell burst at the proper instant, is fixed in it, as in an ordinary shell.

The effect of the musket bullets in the Shrapnel is due to the velocity imparted to them by the gun, and not by the bursting charge which only frees them. A spherical case shot when loaded is about the same specific gravity as a solid shot of the same diameter. A musket ball is effective when impelled with the same velocity as that retained by a solid shot from a 6-pounder or 9-pounder at a range of about 1200 yards. If therefore the spherical case shot be projected by the ordinary service charge, and be made to burst at any distance up to 1200 yards, the musket balls which it contains being freed, will, spreading out like a fan, and covering some extent of ground, strike effectively. For at the instant of the explosion they have the velocity of the shell, and they will proceed forward, generally in the direction in which the shell was going, for the path of the common centre of gravity after explosion will (disregarding the greater effect of atmosphere) be the same as that of the shell before the explosion, and the velocity with which the bullets strike will be the same as that of shell, or at least sufficient to make them effective.

The common spherical case was attended with many inconveniences, and in the larger descriptions of ordnance more especially, was very liable to burst in the gun. This was supposed to be caused by the shell, which was necessarily thin, not being strong enough to resist the explosion of the full service charge; the charge was therefore reduced, but the experiment, besides not being always successful, had the disadvantage of reducing the velocity so much that the bullets were not effective. Captain Boxer, R. A., showed that the cause of the shells bursting was the concussion caused by the different relative motions of the external case and the bullets in the interior, when the former was first put in motion by the charge—a concussion sufficient to ignite the charge of powder. He therefore invented the diaphragm shell, in which the bursting charge is kept separate from the bullets in a chamber formed by a thin iron diaphragm fixed in the shell when it is cast.

The form of the shell will be readily understood from the accompanying cut. It has been found perfectly efficient. The Shrapnel from the Armstrong guns is described under RIFLED ORDNANCE.



Section of Boxer's Diaphragm Shrapnel Shell.

A, the fuze; B to B, the diaphragm; C, C, shell; D, the aperture for inserting bullets, which is afterwards plugged; E, the bursting charge inserted at fuze hole.

SHROUDS. [SHIPBUILDING.]

SHROVE-TIDE, or SHROVE-TUESDAY (from the Anglo-Saxon *scrifan*, to confess), signifies the time of confessing sins; for which purpose this day was anciently set apart by the church of Rome as a preparation for the austerities of Lent. This season was likewise called *Fasting-tide, Fastens*, and *Fast-mass*, by all of which titles it is yet designated in different parts of the North.

In the Reformed Church the ancient practice of shriving or confessing at Shrove-tide is discontinued.

After the people had made the confession required at this season by the discipline of the ancient church, they were permitted to indulge in festive amusements, although not allowed to partake of anything beyond the usual substitutes for flesh; and hence arose the custom yet preserved of eating pancakes and fritters at Shrovetide, which has given this day the vulgar appellation of Pancake Tuesday. The Monday preceding was, by the vulgar, called Collop Monday, a name which it even yet retains in some places from the primitive custom of eating eggs on collops or slices of bread, which the less scrupulous and more luxurious moderns have extended to collops of meat.

On these days of authorised indulgence all kinds of recreations were tolerated, provided a due regard was paid to the abstinence commanded by the Church; and from this origin sprang the Carnival. [CARNIVAL.]

To the pastimes of this early age are also to be traced the diversions of football, cock-fighting, and cock-throwing, as well as the discontinued customs of whipping-tops, roasting of herrings, Jack of Lent, &c., which three last-named sports were evidently meant as types of the rigour of church discipline. The cock-fightings and cock-throwings in England, which have gone into disuse, were once general throughout the kingdom at this season.

(Brady's *Clavis Calendaria*, vol. i.; Brand's *Popular Antiq.*, vol. i.)

SI, in music, the name given by the English, Italians, and French to the seventh of the syllables used in solmisation; and, by the two last, also to the note, or sound, called B by the Germans and English. [SOLMISATION.]

SIALAGOGUES (from *σίαλον*, "saliva," and *ἀγωγός*, "that which leads or brings"), agents which increase the flow of saliva and other fluids from the parotid and other glands in the vicinity of the mouth. They operate in different ways, and are distinguished into local or remote. Of the local, some are gaseous, others are solid; these last are also termed *masticatories*. Of the gaseous, the most familiar is the odour of savoury food, which produces an immediate secretion from the salivary glands, being the primary step in the process of digestion, for the perfect performance of which thorough insalivation of the food is requisite. By the motion of the jaw in the act of mastication a further flow of saliva is occasioned, and this result occurs however insipid or insoluble the substance may be which is moved about in the mouth. Hence even a pebble will cause it. But if the substance possess an agreeable aroma, or a considerable degree of pungency or acrimony, a greatly augmented secretion is the consequence. In hot climates piquant articles are extensively used to stimulate the languid action of the digestive organs. [AROMATICS; FOOD.] In local affections of the mouth, nose, or even head, relief is often obtained by exciting the salivary glands to increased secretion, and this is effected by chewing pellitory root and other pungent articles, or holding in the mouth an infusion or tincture of these. Remote sialagogues are first received into the system by the stomach or other channels, and then exert a peculiar influence on the salivary glands. Of these the most familiar is mercury. This often proves highly remedial, especially in the fevers of tropical countries, in which the occurrence of salivation is always regarded as a forerunner of recovery. In persons whose systems cannot sustain mercury, or to whom it is objectionable, a deficiency of saliva, a frequent accompaniment of indigestion, is removed by the Virginian snake-root, alone, or in combination with preparations of copper.

The excessive salivation which results from even a small dose of mercury should cause the utmost caution to be observed in its use; especially as it is extremely difficult to remove it when once established, or even to mitigate its effects. [MERCURY.] But solution of chloride of soda or infusion of cloves is useful.

SIBYL (*Σίβυλλα*) is the name by which several prophetic women were designated, all of whom belong to the mythical ages of ancient history. But Pausanias (x., c. 12), who gives an account of the sibyls, applies incorrectly the same name to the female soothsayers of the historical times. (Strabo, xiv., p. 645.) It was believed that the sibyls were maidens who were directly inspired with a knowledge of the future, and of the manner in which evils might be averted, and especially of the manner in which the wrath of the gods might be appeased, and that they communicated their knowledge in inspired verses. (Varro, 'ap Lactant.,' i. 6; Cic., 'De Div.,' i. 2; Plat., 'Phædr.,' p. 244.) The number of such prophetesses appears to have been very great in ancient times, and we know of Egyptian, Hebrew, Persian, Babylonian, Greek, and Italian sibyls. Varro enumerates ten sibyls, while others only knew four. (Ælian., 'Var. Hist.,' xii. 35; comp. Suidas, *v.* *Σίβυλλα*.) Varro, however, appears in some cases to make two sibyls out of two epithets belonging to the same person, while on the other hand he does not mention the Hebrew sibyl, Sabbe. (Paus., x. 12, 5.) We shall in this article only mention the most celebrated sibyls.

The most ancient sibyl was Herophile, a daughter of Zeus and Lamia (Paus., x. 12, 1). The Erythraean sibyl was supposed to be a native of Babylonia, but some thought that she was born at Erythrae. She lived before the Trojan war, the cause and issue of which she was believed to have predicted. (Varro; Paus., x. 12, 1.) The Samian sibyl was supposed to have been a priestess in the temple of Apollo Smintheus. She spent the greater part of her life in Samos, but, like most other sibyls, she is described as travelling about and communicating to men her inspired wisdom. Thus we find her at Claros, Delos, and Delphi. She is said to have died in Troas, where a monument was erected to her in a grove sacred to Apollo Smintheus. (Paus., x. 12, 3.) Cumæ in Ionia was also celebrated for its sibyl; but the sibyl of Cumæ in Campania, called Demo, has acquired more celebrity than any other. The ancient legend about her is related by Virgil ('Æn.,' iii. 441, &c.). In the reign of Tarquinius Priscus, or, according to others, in that of Tarquinius Superbus, there appeared before the king a woman, either herself a sibyl or sent by a sibyl, who offered to the king nine books for sale. The king refused to purchase them, whereupon the woman burnt three of the books, and returning, asked for the remaining books the same price as she had asked for the nine. The king again declined purchasing; but when the woman, after burning three books more, returned and asked for the three remaining the same price which she had before asked for the nine, his curiosity was excited, and he purchased the books; whereupon the strange woman vanished. These three books were the Sibylline Books which play such a prominent part in the history of Rome: they contained the "fata urbis Romæ." (Dionys., iv., p. 259; Varro, 'ap Lactant.,' i. 6; Gellius, i. 19; Plin., 'Hist. Nat.,' xiii. 27.) Now who this sibyl was, is differently stated. Some of the ancients represent her as the Erythræan sibyl, others say that she had come from Cumæ in Ionia, and others that she was the sibyl of the Italian Cumæ. Modern writers are likewise divided in their opinions. The Sibylline Books, which were henceforth in the possession of the Roman state, are said to have been written on palm-leaves, partly in verse and partly in symbolical hieroglyphics. The public were never allowed to inspect them, but they were kept in the temple of Jupiter Capitolinus, where they were preserved in a stone chest in a subterraneous vault, and under the care of especial officers (duumviri sacrorum, interpretes, or sacerdotes sibyllæ), who had been appointed by the Tarquinius who purchased the books. These officers had to consult the Sibylline Books (adire libros sibyllinos) on all occasions when the gods manifested their wrath by inflicting calamities upon the Romans, and when human help and human wisdom were not thought capable of averting their anger. The answers which were derived from them were almost invariably of a religious nature, as they either commanded the introduction of some new worship, or the institution of new ceremonies and festivals, or the repetition of old ones. But during the time of the republic, they do not seem to have ever been used, like the Greek oracles, as a means to ascertain the future, or what political measures were to be adopted in order to attain a certain political object. The manner of consulting them, as Niebuhr and others suppose, was probably the following :—they opened the volumes at random, and whatever passage first met their eye was thought to contain the suggestions adapted for the present case. The keepers of the Sibylline Books were at first only two, with two attendants. After the banishment of the kings, the two keepers of the Sibylline Books were appointed by the people, probably in the comitia centuriata, for life. They were exempt from all civil and military offices; and whenever they had to consult the sacred books, they were authorised by a senatus consultum, and they consulted them in the presence of their attendants. The numbers of these priests was afterwards, perhaps in the year B.C. 368, increased to ten, and half of them were to be plebeians: in the time of Sulla their number was increased to fifteen.

In the year 83 B.C. the temple of Jupiter, on the Capitol, was burnt, and the Sibylline Books were consumed by the flames. In order to restore the books, the senate sent ambassadors to various towns of Italy, Greece, and Asia Minor, to collect Sibylline oracles, both from public and private sources. These ambassadors collected about one thousand verses, which were again kept in the temple of Jupiter, after it had been restored. (Dionys., iv., p. 260.) Augustus ordered that all pretended Sibylline books in the possession of private persons should be delivered up to the prætor urbanus, and burnt. On this occasion more than two thousand such books were delivered to the flames; and those oracles which were in the keeping of the state, and were considered to be genuine, were now deposited in two gilt chests in the temple of Apollo, in the basis of his statue, and entrusted, as before, to the quindecimviri. (Suet., 'Aug.,' 31; Tacit., 'Annal.,' vi. 12.) Some years afterwards, Tiberius found it necessary to institute a fresh examination of the Sibylline oracles, and to strike out many which were considered to be spurious. (Dion Cass., lvii., p. 705, Steph.) In the reign of Nero the Sibylline Books were burnt a second time, but were again restored, and used as before. In the year 270 A.D. several members of the senate advised to consult them respecting the issue of the war against the Marcomanni. (Fl. Vopisc., 'Aurel.,' 18.) About this time the Christians, in their zeal to convert the heathens, began to refer to the Sibylline oracles as containing prophecies respecting the Messiah. The collection which was in the keeping of the state was burnt a third time in the reign of Julian (A.D. 363); and a fourth time in the reign of Honorius, by Stilicho, A.D. 395. (Rut., 'Itin.,' ii. 51.) But it was restored each time; and notwithstanding all the forgeries which must have crept into it, the collection continued to be held in great esteem, as it was a useful instrument in the hands of the various parties, political as well as religious. Hence we find the Sibylline Books consulted even as late as the middle of the 6th century of our era.

A complete collection of Sibylline verses was compiled and edited by Gallæus, Amsterdam, 1689, 4to.; but it contains a great many spurious verses, and such as were made by the early Christians who pretended to be inspired. In 1817, A. Mai published a collection of fragments from the Sibylline Books, which he discovered in a manuscript of the library at Milan. Another collection of fragments was published by C. L. Struve, under the title 'Sibyllinorum Librorum Fragmenta,' Regiomont., 1818, 8vo.

SIDE. In modern mathematics this term means nothing but one of the lines which bound a figure, extending from one angle or corner to the next. The Latin word *latus*, of the same signification, is preserved in composition: thus a figure of three sides is trilateral; of four, quadrilateral; of five, quinquilateral; and so on. At the introduction of algebra, the same geometrical analogies by which a number multiplied by itself was called a *square*, procured for the number itself the name of *side;* thus 7 being the side, 49 was the square; and the same of the cube, triangular polygonal, and pyramidal numbers. [NUMBERS, APPELLATIONS OF.]

In common language the side is a vague term, implying only "part, with a notion of relative position;" it is also differently used in and out of composition. First we have the *in*side and *out*side; then, with reference to either of these, we have sides before and behind, above and below, right and left. The first pair is defined by reference to the spectator, the second by the direction of gravitation; but the third, with reference to which the term side is most frequently used, cannot be defined by the mathematician. The anatomist will say, that in the human body, the right side is that on which the heart is not, and the left side that on which it is, and there is no other definition. In every case in which the terms right and left are applied, there is a reference to the position of the human body. Thus the right wing of an army means that which is towards the right hands of those in the centre; as soon as a retreat commences, the names of the right and left wings are changed. The right bank of a river is by convention named on the supposition that the person who names it is looking down the stream, or seeing the water flow from him. Perhaps some may doubt whether the superior and inferior parts, or the anterior and posterior, are in our language properly called sides; these we must remind that the words fore-side and back-side are very good English; and that in the phrase *upside-down* we see the remains of the corresponding phrases up-side and down-side.

SIDEREAL (*sidus*, a constellation; *sideral* would be more correct), applied in astronomy to distinguish that which has reference to the fixed stars, from that which relates to the sun, moon, planets, or comets. See STAR as to general considerations, and TIME as to the distinction between solar and sidereal time.

SIEGE is the process of advancing towards a fortress under the cover of earth thrown up from trenches excavated in the ground; silencing its fire by a superior fire of artillery and musketry; and finally, by breaching the ramparts, either obliging the defenders to surrender, or forcing an entrance into the place.

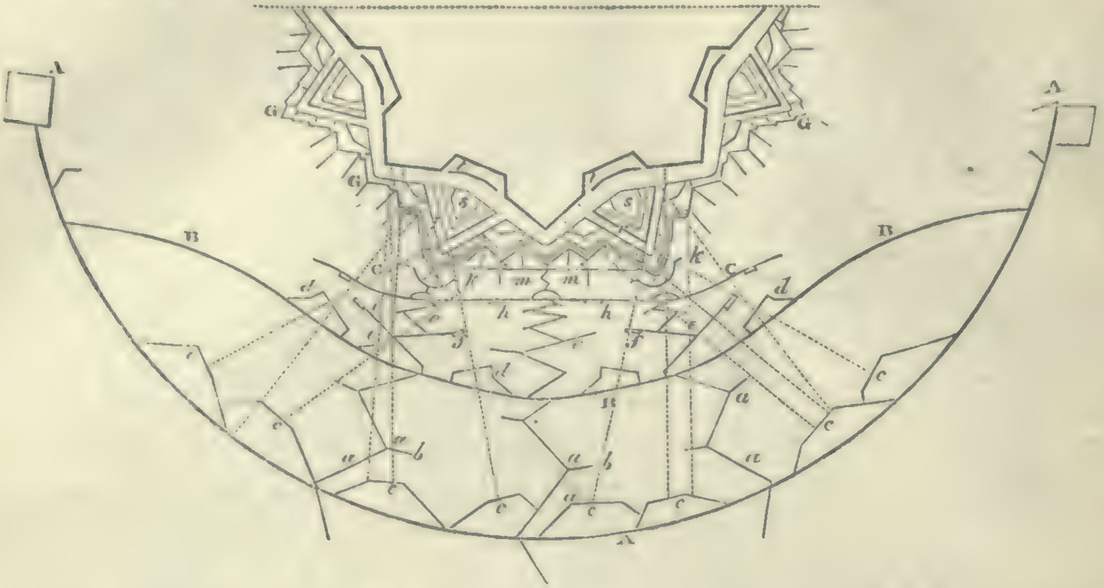
A fortress is invested previously to the commencement of the siege by posting troops about it, so as suddenly to occupy all the avenues to the place, and prevent the garrison from receiving succours. The besieging army, on its arrival, establishes itself in the environs of the place at such a distance as not to be annoyed, by the fire of the artillery of the defenders; protecting itself generally by redouts raised at intervals, both on the side nearest to the fortress and on that which is towards the country. [COUNTERVALLATION.]

The operations of a regular siege, when conducted against places fortified according to any of the modern systems, are nearly the same till the approaches (the oblique lines of trenches) arrive at the foot of the glacis; and when, as in the first system of Vauban, the flanked, or most advanced, angles of the bastions and ravelins are nearly at equal distances from the centre of the place, those approaches may be directed along the produced capitals (lines imagined to bisect the angles) of a ravelin, and of the nearest bastion on each side of it; since then, when the glacis before those works is crowned by batteries, the rampart of the enceinte may be breached in two places at once. But in systems which, like that of Cormontaingne, have very salient ravelins, the approaches should be directed along the produced capitals of a bastion, and of the nearest ravelin on each side, because the glacis of the bastion cannot be crowned till the two collateral ravelins are taken; and if the lines of approach were directed as in the former case, it would be necessary to take three ravelins before either bastion could be breached. The lines of approach are carried on nearly in the direction of the produced capitals of the bastions and ravelins, because here the ground is less subject to the direct fires from the fortress.

In commencing operations, the engineers, having ascertained on the ground the prolongations of those capitals, trace, by means of pickets driven in the ground and connected by tapes, the direction of the first parallel trench, generally termed the First Parallel, A A A, which is somewhere about 600 yards distant* from the advanced parts, G G G, of the covered way. This parallel usually extends along the fronts attacked, and occasionally far enough beyond to embrace the prolongations of all the ramparts, a fire from which might be directed against the works of the besiegers: it should terminate at each extremity, if possible, in some natural obstacle, as a morass or a river; and if no such obstacle exists, a redout may be raised there, in order, by its fire, to oppose any attempt of the enemy to turn the parallel. The trench is executed by numerous working-parties of men, who, being provided with spades and pickaxes, are marched up to the ground after sunset, and are disposed along the line at intervals of four or six feet from each other. The earth obtained from the trench is thrown towards the fortress, in order to form a breastwork; and in the morning the men are relieved by others, who complete the parallel where it may have been left unfinished, and dig trenches obliquely towards the rear, for the purpose of having secure communications to and from the depôts of materials. All the trenches are sunk three feet below the surface of the ground; and the earth thrown out forming a mass about three feet high, the troops in them are effectually covered from the view of the besieged. The general breadth is 10 or 12 feet, but greater width is given in places at intervals from each other, where it may be desirable to collect troops and material.

---

* In the present article we have taken 600 yards as the distance at which the first parallel is established, though it is very probable that in any sieges now undertaken this distance would have to be greatly increased on account of the increased range and power of the arms now in use. 600 yards was the distance generally laid down in text-books as being about the limits at which grape-shot was effective, while it would not be worth while for the garrison to expend their ammunition in firing round shot at men in such extended order, and especially at night. Now, however, unless natural cover could be obtained, it would not be possible to expose men at that distance, for the fire of musketry (rifles) would be very destructive. At the siege of Sebastopol the allies could not break ground anywhere nearer than 1200 yards, and generally from about that to 2000. The distance at which ground can be broken, however, depends so much upon circumstances, such as being screened by houses, hedges, garden-walls, &c., and the effect of the introduction of rifled arms on sieges is so doubtful, that we have retained the ordinary distance given in treatises, as by it the general principle of sieges can be easily understood; and it must be remembered that the explanation refers to a theoretic siege, in which the besiegers are supposed to greatly outnumber the besieged, and in which no disturbing circumstances, such as superior energy and courage on the part of the besieged, the failure of stores, &c., are taken into consideration. The subject is treated in the same manner that we treat abstract problems in mechanics,—disregarding friction.



The first operations of the working-parties take place during the night, in order that some progress may be made before they are discovered by the defenders; but should the latter suspect that ground is being broken, they frequently discharge light-balls, by the light of which they may discover the places where the men are at work. These places being ascertained, it may be expected that the ground will be cannonaded, or that troops will make a sortie from the fortress, for the purpose of interrupting or driving off the workmen; and in order that this intention may be frustrated, the parties are accompanied by a guard of infantry, or covering party, which is placed at about 50 yards in front of the tracing-line. These troops obtain cover if possible, or lie down on the ground, that they may not be exposed to the defenders' fire; and in the event of a sortie being made, they are ready to repel it: squadrons of cavalry are also, if the ground permits it, stationed near the extremity of the parallel, that by a rapid movement they may take in flank and cut off the retreat of the sortie.

The general uses of the parallels are to connect the lines of approach by a covered line of communication, to allow the trenches to be kept clear of troops and free for the workmen, and, affording cover and protection to the guard of the trenches and a strong position for them to remain in during the day, to serve as lines of countervallation in confining the garrison of the place. As soon as the first parallel is finished, the guard of the trenches is moved into it, for the purpose of protecting the succeeding operations. While the approaches are being pushed forward, or indeed while the first parallel is being completed, the batteries C, C, C...., are formed either in or in advance of the first parallel to keep down the fire of the place either by direct or enfilade fire as shown by the dotted lines.

Since the trenches leading from the first parallel towards the place ought not to be enfiladed from thence, it is evident that they must be formed in zig-zag or oblique directions *a a a*, &c., crossing and recrossing the produced capitals of the bastions or ravelins; and that the several branches, if produced, should fall on the exterior of all the works of the place. The first oblique *boyeau* (branch) of the trench may be defended by the fire of the parallel; but the second may, if found necessary, be protected by the fire of troops stationed in a small trench, *a b*, called a parallel boyeau, at the angle between the first and second branches; and a short branch for the like purpose is generally formed at the angles of all the zig-zag trenches. If the directions of the several oblique branches are not laid down on the ground, from a plan of the intended operations previously made on paper, the engineer endeavours, during the daylight, to observe, in the direction of the most advanced part of the glacis towards his right or left hand, some object towards which the tracing-line may be stretched and the trench carried on. These trenches are then executed by the working-parties, in the same manner as the great parallel was formed. At the siege of Badajos, in 1812, a French corporal, in the dusk of an evening, dexterously displaced a tracing-line, which had been stretched by the British engineers, and directed it so that the trench executed along it might have been enfiladed by three guns on the ramparts of the castle. If the derangement had not been discovered before darkness came on, the labour of the whole night would have been lost, and casualties might have occurred from the fire which the garrison might have directed along the trench. The workmen are usually relieved after it is dark, in order that the change may not be observed from the fortress; but the officers should be relieved earlier, that those who come on duty may have light enough to examine the actual state of the works, and to take measures for directing the operations of the men during the night.

When the heads of the trenches have arrived within 300 yards of the covered-way, which is usually about the fourth night from the time of opening the trenches, a second parallel, B B B, is formed, in order to facilitate the communication between the several lines of approach, and to protect the working-parties, for it is evident that having got half way between the first parallel and the place, as the boyeaux advance the working-parties in them are nearer to the enemy than to their supports. This trench may be extended along the particular points attacked, and its extremities may be terminated by redouts, or continued till they fall into the first parallel. It is executed by flying sap [SAP], that the men may be quickly protected from the fire of musketry in the covered-way, which might now begin to take effect.* One of the principal means of accelerating the surrender of the fortress is that of enfilading the ramparts, in order to dismount the guns and drive the defenders from the parapets. But in order to be effective, the range for ricochet fire should be short; for this reason fresh batteries, *d d d*, &c., are raised in the directions of the produced faces of the works, in or near the second parallel, which thus may form a secure communication between them, and are armed with guns moved up from the first parallel. [BATTERY; RICOCHET.] From the same batteries also an oblique fire may sometimes be directed against the interior of the flanks and curtains, and a plunging fire into the ditches, in order to impede the communication between the place and the outworks. All the different ricochet batteries commence firing at the same time, that the attention of the defenders may be divided, and that they may be prevented from concentrating all their fire upon one battery; the guns also should be fired singly, and at intervals so regulated that there may be always some shot or shells in the air, for thus the enemy will have little time to repair the damage done to his artillery or to the parapets. The firing should be commenced during daylight, in order that the artillerymen may be able to determine by trial the charge of powder and the degree of elevation for each piece, so that the shot may just clear the parapet of the work to be enfiladed; this being obtained, the direction of the piece may be preserved by means of timbers nailed to the platform, and thus the fire may be kept up with equal accuracy by night and by day.

After the fire from the ricochet batteries has partly silenced that of the place, the trenches of communication are continued in zig-zag directions as before, and with the like precautions against being enfiladed from the fortress and its covered way. These and all the succeeding trenches may be executed by full sap [SAP], while the fire of the besieged continues in activity; but if that fire should become at any time relaxed, the opportunity may be seized of carrying on some part of the approaches in a more expeditious manner. When the heads of the oblique trenches are about half-way between the second parallel and the foot of the glacis, a demi-parallel, *e e*, &c., is carried out on each side of the produced capitals of the works attacked, till it meets the prolongation of the crest of the covered-way: its use is to protect the works which are to be executed in its front by a fire of musketry, which, being nearer, is more effectual than that of the second parallel. Howitzer batteries, *ff*, &c., are formed at the extremities of these parallels for the purpose of enfilading the covered-way with shells, and thus destroying the palisades and traverses. As soon as the fires from the howitzers have produced some effect, the oblique trenches may be continued till they arrive at the foot of the glacis, on the capital of each of the works attacked, the branches being directed, as before, towards the exterior of any part of the covered-way from whence the enemy might enfilade them; and each being prolonged towards the rear about 10 or 12 yards, in order to form places where tools and materials may be deposited out of the line of passage along the trenches. If the defenders should have established redans or redouts at the foot of the glacis, or should have carried out counter-approaches from any of the collateral works, in order to enfilade the trenches of attack, they must be assaulted and destroyed as soon as it is found that the fire from thence impedes the operations of the besiegers.

---

* It must be understood that this refers to smooth-bored fire-arms.

A third parallel trench, C C, may now be executed to connect the points of attack at the foot of the glacis; for this purpose the squads of sappers turn to the right and left from the head of each line of approach, and meet each other, forming as they proceed a trench which is either rectilinear or curved towards the re-entering parts of the fortress, in order to enable the troops in it to fire less obliquely on the branches of the covered-way. This parallel should be made broader than the others, because considerable bodies of troops are occasionally collected in it, and at intervals steps should be made in it long enough to allow a company of men to mount in line over the parapet. For the protection of the troops, the crest of its parapet should be furnished with sand-bags disposed so as to leave between them small intervals (loop-holes) to fire through; and in this parallel, batteries, *h h*, &c., for small mortars may be formed, in order that shells may be thrown from thence into the principal works. It is estimated that the third parallel may be finished by about the tenth night from the time of opening the trenches.

At this period, should any great necessity exist for hastening the surrender of the place, should also the garrison be weak, and should there be no retrenchments in the covered-way, it may be thought proper by main force to assault the latter, and immediately crown the glacis with batteries for breaching the works. In this case, the defenders should be driven as much as possible from the covered-way by a heavy fire from the mortar and howitzer batteries; then the troops who are to make the assault, having been assembled in the third parallel, mount, at a signal a little before sun-set, over its parapet, and proceed rapidly up the glacis. A party of men then extend themselves along its crest, and by their fire keep down that of the defenders on the parapets; in the meantime the sappers commence forming with gabions a lodgment on the crest, and the rest of the storming party endeavour to force an entrance through breaches made by artillery in the palisades. When the defenders have thus been compelled to retire behind the traverses in the covered-way, the assailants, who then become exposed to the fire from the parapets of the bastions or ravelins, retire into the lodgment which by this time may be finished on the crest of the glacis; and during the night there may be executed trenches of communication from the lodgments to the third parallel. The lodgments thus formed may be afterwards connected together, and extended to the right and left if necessary; and in these the breaching batteries may be formed.

Should the fortress have small ravelins, like those of Vauban, the assault may take place at once on the salients of a ravelin and of the two collateral bastions; but if the ravelins advance far towards the country, as in Cormontaingne's system, it can take place only at the salients of the ravelin on each side of one bastion; since if it were attempted to carry on the approaches between the two ravelins, the troops and sappers would become exposed to fires on their flanks and in rear as well as in front.

An assault [ATTACK] by main force is always attended with considerable loss, and therefore, if time permits, it is preferred to continue carrying on the approaches by sap. For this purpose, supposing the place to be fortified with large ravelins (as in the cut), a trench is begun at about 30 yards on each side of the ridge between the two faces of the glacis before the ravelins only, and carried in a curvilinear direction till the two squads of sappers meet on the ridge about eight or nine yards in advance of the third parallel. From hence the trench is continued by double and direct sap along the ridge till it arrives at between 30 and 40 yards from the crest at the angle of the glacis; and at this spot, formerly, high breastworks, called trench cavaliers, *k k*, &c., about the thirteenth night from the time of opening the trenches, were raised on the prolongations of the branches of the covered-way, in order to allow a plunging fire of musketry to be directed into those branches. But as the fire of the defenders' artillery may prevent the construction of such works, instead of them there are now formed batteries armed with small mortars from which balls or stones may be projected into the covered-way in order to compel the defenders to retire from thence. (Mortars for throwing stones are called by the French *pierriers*.)

After the fire from the cavaliers or mortar-batteries has obliged the enemy to abandon the advanced parts of the covered-way, double saps are carried on towards the salient angle of the glacis, and when they have arrived at about 24 feet from that angle, the crowning of the glacis commences. This is performed by extending the sap along the crest on each side of the angle, and throwing up the earth towards the place in order to form epaulements for batteries. That the crowning trenches may be secured against the enfilading fires from the collateral works of the besieged, traverses are formed across them at intervals in situations where they may not interfere with the guns to be placed in the batteries; and, on account of the fire which the enemy may still keep up from the branches of the covered-way and the retrenchments in the re-entering places of arms (see the figure in art. FORTIFICATION), a portion of a fourth parallel, *m m*, should now be carried out in order that troops placed there may protect the sappers during the formation of the batteries, and the artillerymen during the operation of breaching the ravelins. The crowning of the glacis is sometimes extended along the faces of the re-entering places of arms; and in this case trenches on those faces are connected with the fourth parallel by lines of communication formed in serpentine directions.

The epaulements raised by the besiegers between the salient angle of the glacis and the first traverses on each side are to serve as counter-batteries, whose use is to ruin the parapet and dismount the guns in the faces or flanks of the collateral works, in order as much as possible to prevent the enemy from opposing by musketry or artillery the passage which is to be effected across the ditch; and the epaulements between the first traverses and the re-entering places of arms serve for the breaching batteries. [BREACH.] The crowning batteries on the glacis of two ravelins, *r r*, are supposed to be finished about the sixteenth night from the time of opening the trenches.

While the breaches are being formed, the passages by which the descents into the ditches of the ravelins are to take place are commenced. These are either open trenches or subterranean galleries cut in inclined planes through or under the covered-way opposite the breaches; each passage thus terminates at a perforation in the counterscarp about 3 feet above the bottom of the ditch if dry, or at the level of the water if it contain any. The sappers throw fascines into the ditch if dry, till the heap is sufficiently high and thick to secure them from the fire of the defenders, and then getting in, they form by sap a trench and parapet extending some way up the breach itself. Preparations are afterwards made for the assault.

For this purpose the interior of the batteries and the passages leading to the ditches are during the night filled with troops, in whose rear are bodies of sappers with their materials; and early in the morning, after a heavy fire has been for some time kept up from the batteries in order to drive off the defenders, the troops charge up, and endeavour to keep the enemy engaged while the sappers execute lodgments on the breaches by filling their gabions with the loose earth; as soon as these are finished, the storming parties retire behind them, and from thence keep up a fire upon the enemy. These lodgments should if possible be on the tops of the breaches, but if the interior of the ravelin is retrenched by a redout, as *s s*, whose fire commands those spots, the lodgments must be formed on the ascent, that they may not be immediately destroyed. It is estimated that the two ravelins may be taken about the eighteenth night.

If the ditches contain water which cannot be made to flow off, there may be formed across them solid causeways consisting of fascines laden with stones to make them sink, or of casks or gabions having their axes in horizontal positions; or floating-bridges of timber-logs, casks or pontoons may be constructed; and by any of these means the troops may pass over to the assault. From the lodgments just mentioned trenches are carried on by sap directly to the top of the breach, and from thence turning to the right and left they are continued about half-way down the faces of the ravelins: their extremities being made to join the parapets of these works.

The redouts in the two ravelins are next to be taken; and to effect this object, it being supposed that the faces of the ravelins are too narrow to allow room for forming batteries on them, either a portion of the ravelin must be blown up in order to allow the fire of the breaching-batteries on the glacis to act against the redouts through the apertures, or else the redouts must be breached by undermining them. Should the latter method be preferred, a trench or gallery is cut through the mass of each ravelin, and a sap is carried across the ditch of the redout; the miner then, being secured against the effect of the enemy's grenades by timbers placed in inclined positions leaning against the scarp of the redout, cuts through that scarp and forms chambers for the reception of gunpowder. This being fired, a part of the rampart will be destroyed and a breach formed. An assault is then made by troops, and the defenders being supposed to be driven out of the works, a battery may be raised along the gorge of each redout in order to compel them to quit the tenailles, *t t*, in the main ditch. The redouts of the ravelins being taken (probably about the twenty-first night), the defenders will also be obliged to retire from the rear extremities of the latter works; and the besiegers occupying those extremities, their fire from thence commanding the interiors of the redouts in the re-entering places of arms, these last must also be abandoned.

The approaches towards the bastions may now be recommenced, as the fires from the ravelins are no longer to be apprehended; therefore a double sap is carried on from the curved trench in the third parallel directly along the ridge of the glacis, till it begins to be plunged into by the fire from the bastion: it then proceeds in a serpentine direction till its head arrives between the portions of the fourth parallel already formed. This parallel is then completed, and under the protection of the fire from the troops stationed in it, the counter and breaching batteries before the bastion are formed. By the former the fire from the guns in the flanks of the collateral bastions is partly silenced, and by the latter the breach in the faces of the opposite bastion is effected. The passage through the counterscarp and a trench across the main ditch are then executed, and an assault may be made up the breach of the bastion, similar to those which had been made up breaches of the ravelins; the defenders being repelled, a lodgment may be formed, and unless the bastion is strongly retrenched, it may be expected that the place will now be surrendered. It is estimated that the assault of the bastion may take place about the twenty-sixth night from the time of opening the trenches; but a good retrenchment [RETRENCHMENT] in a bastion may enable the defenders to hold out ten or twelve days longer.

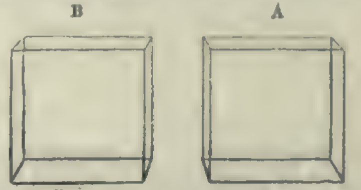
A fortress is said to be countermined when subterranean galleries are formed under the ramparts of the bastions and ravelins; under the covered-way, and under the ground at the foot of the glacis, with galleries of communication from one of these to another. And as the defenders can form chambers and place powder in or near any convenient parts of these galleries to destroy the works of the besiegers above-ground, the besiegers find themselves under the necessity of sinking shafts and forming galleries for the purpose of finding out and destroying those of the defenders, or of blowing up any of their advanced works. [MINES, MILITARY.]

A siege conducted according to the rules of art will be attended with comparatively small loss to the besiegers or besieged, the troops of both parties being but little exposed to each other's fire except at the times when the assaults are made on the ravelins or bastions. And if circumstances, such as the prospect of the place being relieved, did not compel the besiegers to expedite the surrender, the assaults by main force might be avoided; for after a breach has been formed, and the parapets of the place have been in a great measure ruined by the artillery of the besiegers, a sapper might be sent across the ditch by night with instructions to commence a trench under cover of one extremity of the broken wall; then, if he succeed in getting cover for himself, others may follow, and gradually there may be formed on the breach a lodgment sufficiently large to contain troops, whose fire would protect the succeeding operations: it being understood that a firing party in the batteries on the glacis force the defenders to retire as often as they endeavour to disturb the sappers while at work.

The want of time and means to carry on the approaches as far as the covered-ways was the cause of the great losses sustained in getting possession of the fortresses garrisoned by the French in Spain during the Peninsular war. The breaches in the walls of Badajos (1812) were made by guns in batteries at the distance of 500 yards; and when the assailing troops had descended into the ditch, being ignorant of the positions of the breaches, and confused by the darkness of the night, which was relieved only by the appalling and destructive blaze of live shells and other combustibles thrown upon them from the parapets, they took a wrong direction, or remained patiently to be slaughtered till the order was given to retire. The effort would have entirely failed, but for the success of Major-General Picton in escalading the walls of the castle, and of General Walker in escalading the bastion of S. Vincente.

SIGHT (vision, the faculty of seeing). The structure and uses of the several component parts which enter into the formation of the organ of vision have been already described in the article EYE, in NAT. HIST. DIV. We have now to inquire by what means the images of objects which are depicted on the retina become converted into ideas of the objects themselves; of their proximity and distance; of their solidity and size. In other words, is the interpretation of the sensations of the retina a vital property of the structure itself, or is it in part derived from other sources? The following case, which is recorded by Cheselden, affords us important data on this head. A young man, who was born blind, was suddenly restored to sight by the operation of couching. "When he first saw," observes Cheselden, "he was so far from making any judgment about distances, that he thought all objects whatever touched his eye (as he expressed it), as what he felt touched his skin. He knew not one thing from another, however different in shape and magnitude; but upon being told what things were whose form he before knew from feeling, he would carefully observe, that he might know them again. Two months after being couched, his attention seems to have been drawn to the effects of painting, which he then first and at once comprehended; but even then he was no less surprised, expecting the pictures would feel like the things they represented, and was amazed when he found those parts which by their light and shadow appeared round and uneven, felt only flat like the rest, and asked which was the lying sense, feeling or seeing? Being shown a small miniature of his father, and told what it was, he acknowledged a likeness, but was vastly surprised, asking how it could be that a large face could be expressed in so little room, saying it should have seemed as impossible to him as to put a bushel into a pint. At first he could bear but very little light, and the things he saw he thought extremely large, but upon seeing things larger, those first seen he conceived less, never being able to imagine any lines beyond the bounds he saw. The room he was in, he said he knew to be but part of the house, yet he could not conceive that the whole house could look bigger." From the details of this interesting case, it would appear that the sense of sight (so far as we can judge of it when performed with one eye, for only one had been operated on when the above phenomena were observed) originally gives us no information respecting the solidity, the distance, or the real magnitude of objects; but that they all seem as if painted on one surface. If this then is the sum of the information which is conveyed to us by the retina; if it is limited to the mere perceptions of the images of objects, and conveys to us ideas relative to superficial extent only, it is clear that our estimation of the true position, the magnitude, and solid forms of bodies must be due to some other sense than that of sight, or rather, to a comparison of some other sense with it; in short, to an act of our comparing and reasoning faculties.

We have seen by the details of the above quoted case, that there is no essential resemblance between the ideas which are derived from vision and those communicated by touch; and it is no doubt partly owing to this circumstance that we obtain a correct knowledge of external objects through our visual organs. The lad couched by Cheselden could not recognise by sight the things whose form he before knew from feeling; but upon being told what they were, he would carefully observe, that he might know them again. The infant, in like manner, stretches out its little hands to grasp and examine each object in succession which attracts its sight, and the greater part of its waking hours is employed in thus comparing the sensations obtained through these two different channels. That we do acquire important information respecting the size and forms of bodies through the sense of touch there can be no doubt; that the knowledge obtained through our visual organs would be imperfect without it, and that it may in some measure be a corrective of those optical illusions which are so frequent when we attempt to judge of things by sight alone, is equally probable; but in admitting this, we must not underrate the original powers of the eye and the quantity of knowledge which we primarily derive from it. From some facts we are about to notice, it would appear that much of the information which we derive from our visual organs only, has hitherto been attributed to extraneous sources. Physiologists have been too much swayed by the opinion of Gassendus, Haller, Gall, and others, that we see with only one eye at a time, and those even who disputed this have been more anxious to explain why objects are seen single with both eyes than to inquire into the uses of our possessing two. These defects, which are more or less common to all writers on optics, have been some years since remedied by some very interesting observations of Professor Wheatstone on Binocular Vision. He has shown that the simultaneous affection of the two retinæ, provided the optic axes are not parallel, excites a different idea in the mind from that consequent on either of the single impressions; the latter giving rise to a representation on a plane surface, the former to that of an object in relief. This is owing to a different perspective projection of the object being seen by each eye; thus, if any figure of three dimensions, an outline cube for example, is held at the distance of about seven inches before the eyes, and viewed with each eye successively while the head is kept perfectly steady, A will be the picture presented to the right eye, and B that seen by the left. Now if these two pictures are made to fall on corresponding parts of the retinæ, by placing them one in the direction of each optic axis at equal distances before or behind their intersection, the mind will perceive not merely a single representation of the object, but a body projecting in relief, the exact counterpart of that from which the drawings were made.

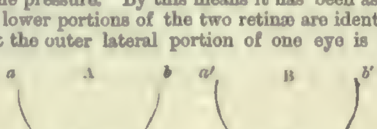


But a better method is to employ the stereoscope, an instrument invented for the purpose by Mr. Wheatstone, the essential parts of which are two plain mirrors inclined with their backs towards each other at an angle of 90°. The two pictures A and B are placed in the same horizontal line, and parallel to each other at the sides of these mirrors, and at equal distances from them. The observer then placing his eyes as near as possible to the two mirrors, their angle coinciding with the middle line of his forehead and face, sees the solid body represented by the perspective drawings standing forward in relief, provided the two drawings are so situated that their images reflected by the mirrors coincide with the lines of the convergent optic axes. Instead of the original reflecting stereoscope of Mr. Wheatstone, an instrument of the refracting form introduced by Sir David Brewster, and now so common, may be used in the experiment. When similar images, differing to a certain extent in magnitude, are presented, by means of the stereoscope, to corresponding parts of the two retinæ, a single object, intermediate in size between the two monocular pictures, is seen. Were it not for this, objects would be seen single only when the optic axes converge directly forwards; that is to say, when the object is equally distant from the two eyes; for it is only then that the images on the retinæ can be of equal size, the size of the image being dependent on the angle under which the object is seen, and this being less as the object is more distant. As our conviction then of the solidity and projection in relief of bodies depends upon a different perspective image of them being presented to each retina, and as this can only take place when the axes of the eyes are made to converge to them, it follows that when objects are at such a distance that in regarding them the optic axes are parallel, their images on the retinæ will be exactly similar, and the idea conveyed to the mind will be the same as if they were seen with one eye only. Hence, when two perfectly similar pictures of an object are viewed in the stereoscope, although they coalesce, they appear but as painted on a flat surface. With a knowledge of these facts, it becomes easy to explain why the artist is unable to give a faithful representation of any near solid object, that is, to produce a painting which shall not be distinguished in the mind from the object itself. When the painting and the object are seen with both eyes, in the case of the painting two similar pictures are projected on the retinæ; in the case of the solid object the pictures are dissimilar; there is therefore an essential difference between the impressions on the organ of sensation in the two cases, and consequently between the perceptions formed in the mind; the painting therefore cannot be confounded with the solid object. As our belief then in the solidity of a near object is owing to our taking cognisance of the impressions on both retinæ, it is interesting to inquire whether any other kind of information is imparted to us by the possession of two eyes, which we should not obtain by one only. It is well known that if we close one eye, and attempt to judge of distances with the eye that remains open, our conjectures are wide of the mark, and the rationale of this has been explained by Le Cat, in his 'Traité des Sensations,' in the following words:—"The concurrence of the optic axes, and the length of the angle they form, are the fundamental principles for estimating the distance of objects: hence it is that when we look with one eye only, we are unable to distinguish distances, and cannot place the end of the finger directly upon an object indicated to us, though it be very near, for the finger hides the object, and appears to correspond to it as exactly when it is at the distance of a foot, as if it were only a line removed from it. But if our other eye be open, it will see the finger and the object from the side, and will therefore discover a considerable interval between them if they are a foot distant from each other, but only a very small interval if they are very near; and thus we are enabled to place our finger with certainty upon the desired object."

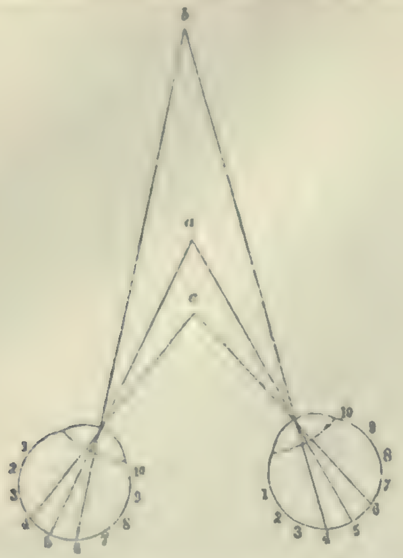
The convergence of the optic axes which takes place when we regard objects within a short distance of us, is supposed by many to assist us in our judgment of the magnitude of bodies, and if this is admitted, it is another proof of the variety and extent of information conveyed to the mind by the possession of two eyes, which a single eye could only have afforded with the aid of the movements of the head and of the sense of touch. The confusion of vision and the indetermination of judgment which follow the loss of an eye, often continue for many months, and strikingly illustrate the truth of the foregoing remarks. Our estimation of the distance and size of remote objects is purely a matter of experience; an object appears distant in proportion to its indistinctness of colour and outline, to the number of intermediate bodies seen between it and the observer, and to its appearing relatively smaller than these. We judge of the magnitude of objects by a calculation founded on their apparent size and probable distance: hence we are liable to continual mistakes on these points. An Englishman in the clear atmosphere of Italy supposes distant objects to be nearer to him than they are. A mountain which we see at a distance for the first time appears generally much less than it really is, and we think it near us when it is very far away. From these remarks it is evident that the mind is constantly co-operating in the acts of vision, so that it becomes difficult to say what belongs to mere sensation, and what to the influence of the mind: that the latter must take an active part in the conceptions of vision, is evident from the great difference in the extent of the actual and the mental field of vision. The one is dependent on the extent of the retina; the other has no determinate limits: in one, all objects are of equal magnitude that are seen under the same angle, and therefore produce an image of the same size upon the retina; in the other, the images of these objects though viewed under the same angle, are of various sizes and placed at very different distances.

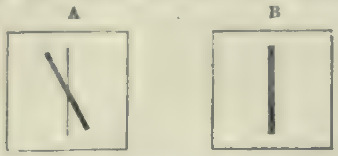
It is scarcely necessary to say much in reference to the movement of bodies: we judge of their motion partly from the movement of their images over the surface of the retina, and partly from the movement of our eyes following them. If the image upon the retina moves while our eyes and body are at rest, we conclude that the object is changing its relative position with regard to ourselves. In such a case the movement of the object may be apparent only, as when we are fixed upon a body which is in motion, such as a ship. On the other hand, the image may remain fixed on the same spot of the retina, while our eyes follow the moving body; we then judge of its motion by the sensations in the muscles which move the eyes. If the image moves only in correspondence with the actions of the muscles, as in reading, we infer that the object is stationary. The sensations of rotatory movements of objects, produced by turning the body on its axis, are quite independent of any impressions on the retina, and their consideration is therefore foreign to the subject we are treating of. The apparent movement of objects after looking at those really moving, may arise from the successive disappearance of spectra left by the moving bodies. From the fact that artificial excitement of the retina, either by pressure, electricity, or any other cause, gives rise to the perception of colour as well as light, we infer that the retina is the seat of these sensations. The colour of luminous bodies depends upon the quality of the light they emit; the colour of bodies that are not luminous is due to the light which falls upon them, and is reflected by them towards our eyes. When a body absorbs all the rays of light which fall upon it, its colour is black; when it reflects them all, it is white; and when it absorbs some and reflects others, it is coloured. [ABSORPTION.] The question has often been raised, why is it that we see objects erect, while their images on the retina are inverted? According to most physiologists, it is by virtue of a certain property of the retina by which each point of an object is seen in the direction of a line perpendicular to its surface; now since this surface is concave, the rays proceeding from an object which fall on the lower part of its concavity will incline upwards, while those which impinge on its upper part will incline downwards; and thus the object presented to the mind will be the reverse of that which is depicted on the retina. Many physiologists reject this theory, on the ground that it involves an impossibility, since each point of the image is not formed by rays having one determinate direction, but by an entire cone of rays; they affirm moreover that vision can consist only in the perception of the state of the retina itself, and not of anything lying in front of it in the external world. They argue further, that no explanation of erect vision is required, as long as all things equally, and not some objects only, appeared to the eye inverted; for nothing can be inverted where nothing is erect, each idea existing only in antithesis to the other. A question not less agitated than the one we have just discussed, is that of single vision with both eyes. We shall not inquire into the merits of the various theories that have been invented in order to account for this phenomenon; but shall merely advert to the principal conditions which are essential to single vision, in order that we may explain under what circumstances double vision results.

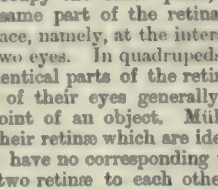
If two fingers are held up before the eyes, one in front of the other, and vision is directed to the more distant, the nearer will appear double, while if the nearer one is regarded more particularly, so as to appear single, the more distant will be seen double, and one of the double images in each case will be found to belong to one eye, and the other to the other eye. This phenomenon has given rise to the hypothesis that there are certain corresponding or identical points on the two retinæ, and that when these are affected simultaneously, single vision results; while if the image of an object falls on parts which are not identical, it is seen double. A knowledge of these facts is obtained in the following manner:—If in a dark room with our eyes closed we make pressure with the finger upon any part of the ball of the eye, so as to affect the retina, a luminous circle will be seen in the field of vision at the opposite side to that on which the pressure is made. If we press on both eyes simultaneously, *one* luminous ring is seen when "identical" parts are pressed on, and *two* rings when "non-identical" parts receive the pressure. By this means it has been ascertained that the upper and lower portions of the two retinæ are identical with each other, and that the outer lateral portion of one eye is identical with the inner portion of the other, and so of the intermediate parts. Now whenever the axes of our eyes converge to an object, its image falls on corresponding portions of the two retinæ, and is seen single; when we regard it without making our optic axes meet in it, as in the experiment of holding up two fingers, non-identical parts of the retinæ are affected, and it is seen double. To illustrate this, let *a* be a point towards which the axes of the eyes are directed, and *b* an object more distant from the eyes. An image of *a* will fall upon identical points of the two retinæ, namely, upon the central points 5, 5; *a* will consequently be seen single. The image of *b* will fall in the left eye at 6, and in the right eye at 4. The points 4 and 6 of the two eyes being non-identical (since the identical parts are marked with corresponding figures), *b* will be seen double; and the distance between the two images of *b*, in proportion to the extent of the whole field of vision, will be the same as that between 4 and 6, in comparison with the distance between 1 and 10 in each retina. The centre of the retina furnishes the most distinct vision, therefore double images, which generally fall on the lateral parts, are indistinct. The position of double images depends upon the point at which the axes of the eyes decussate; if in front of the object, the left hand image belongs to the left eye, and the right hand image to the right eye; while if the axes converge to a point beyond it, the converse of this is observed. That objects will not in general be seen single, unless their images fall on corresponding portions of the two retinæ, is further confirmed by the phenomena which are observed in strabismus, and by the experiment of displacing the axis of one eye by



pressing on it with the finger; but that exactly identical points of the retinæ must be affected by similar points of the two images, is sufficiently refuted by Mr. Wheatstone's discovery of different perspective projections being presented to each eye. Mr. Wheatstone has also shown that under some circumstances similar pictures falling on corresponding points of the retinæ may appear double and in different places. If to one eye we present in the stereoscope a vertical line B, to the other eye a line inclined some degrees from the perpendicular, we shall see a line the extremities of which appear at different distances before the eyes. If now we draw a faint vertical line, intersecting the inclined line at its centre, as at A, and present the two drawings to the eyes as before; the two strong lines will still coincide, and the resultant perspective line will occupy the same place, while the faint line, though it occupies the same part of the retina as the vertical line B, appears in a different place, namely, at the intersection of the planes of visual direction of the two eyes. In quadrupeds the relation between the identical and non-identical parts of the retinæ cannot be the same as in man, for the axes of their eyes generally diverge and cannot be made to meet in one point of an object. Müller therefore supposes that there are parts of their retinæ which are identical, and parts which are not identical, which have no corresponding parts in the other eye, and the relation of the two retinæ to each other in the field of vision may be represented as below. Although the theory of corresponding points is the most perfect that has yet been offered in explanation of the phenomena of single and double vision, yet the facts which have been advanced against it by Mr. Wheatstone are sufficient to show that it cannot be adopted without some limitation. Were it even not liable to these objections, it would still only express the *conditions* required for single and double vision, and would leave unexplained the *cause* of two impressions giving rise to one sensation.







There are several curious phenomena connected with the subject we are treating of, some of which we will briefly allude to. If a piece of white paper is viewed through two different coloured glasses, held one to each eye (for instance, through a blue and a yellow glass), the paper is not seen of a green colour, or rather of the whitish colour which would result from the strict mixture of the two colours, but in part blue and in part yellow. Sometimes one colour predominates, sometimes the other; and if the experiment is long continued, the mingling of the colours, to which there was at first no tendency, becomes more evident. Similar phenomena are observed when two dissimilar pictures are viewed in the stereoscope, and it does not appear to be in the power of the will to determine the appearance of either picture or either colour. These facts seem to show that the two eyes are not always in action together; but that at one time the sensations of one eye predominate, and at another those of the other. If the eyes are closed after being fixed for some time on an object, we still continue to see its image, and the duration of this image, or "spectrum," as it is called, is in a direct ratio with the impression which caused it.

Spectra left by the images of white or luminous objects are ordinarily white or luminous, and those left by dark objects dark; but if, instead of closing the eyes, they are directed upon some white surface, as a sheet of paper, the colours of the spectra are reversed, those which were white when the eyes were closed becoming black when directed to the white surface, and *vice versâ*. These phenomena are easily explained. The part of the retina which has received the luminous image remains for some time afterwards in an excited state, while that which has received a dark image is in an unexcited and therefore much more excitable condition. When the eye in this condition is directed towards a white surface, the luminous rays from this surface produce upon the excited parts of the retina a much more feeble impression than upon the unexcited, and the latter consequently appear more illuminated. Spectra are sometimes coloured, although the objects which excited them are colourless; such is the case if the impressions on the retina are very intense, as when produced by the sun's image. But the most curious phenomena relative to ocular spectra arise from the impression of coloured objects on the retina; the spectra consequent on these, although coloured, are not of the same colour as the object, but the opposite or complementary colour. Thus the spectrum of a red object is green, that of a green object red, that of a violet yellow, &c. There are two modes of explaining these phenomena, the least objectionable of which is the following, offered by Muller: "The perception of any one of the three simple colours consists merely in the retina being in one of those conditions to which it has a tendency when in a state of excitement; if this condition be artificially excited in an intense degree, the retina acquires an extreme tendency to that of the complementary colour, which consequently is perceived as the ocular spectrum."

The disappearance of images which fall on the retina at the entrance of the optic nerve, the luminous circles seen on making pressure with the finger on the globe of the eye, and the vascular network which, under certain circumstances, we perceive in our own retina, have already been alluded to and their causes explained in the article EYE, in NAT. HIST. DIV.

SIGHT, DEFECTS OF. Under this head will be comprehended short-sight, long-sight, double vision, and the defective perception of colours, or colour blindness.

Myopia, or *Near-sightedness* (from μύω, "I shut," and ὤψ, "the eye," a short-sighted person being in the habit of winking, or half shutting his eyelids when he endeavours to see objects distinctly).

When the images of surrounding objects are brought to a focus in the eye before they reach the retina, such an eye is myopic; when, on the contrary, their foci would fall behind the retina, it is presbyopic. Individuals thus affected see all objects indistinctly that are viewed at the ordinary distance of distinct vision; therefore, to remedy this defect, they bring them within such a distance of the eye as will ensure their images being brought to an exact focus upon the retina. The point of distinct vision (that is, the distance from the eye at which objects are perceived most clearly) of a perfect eye averages from 15 to 20 inches: an eye which cannot discern objects distinctly beyond 10 inches may be considered myopic; but persons affected with a high degree of myopia have their point of distinct vision as near as two or three inches, or even one inch, to the eye. To short-sighted persons all objects appear magnified; they prefer to read a small type, and see better through a pin-hole in a card than with the naked eye: on the same principle, when they endeavour to see any distant object distinctly, they almost close their eyelids. The explanation of these phenomena is to be sought for in the condition of the eyes themselves; they are generally firmer than usual, their corneæ are preternaturally convex, and their pupils large; hence by diminishing the aperture through which the light is admitted, all but the more direct rays are excluded, and the images on the retina will be more defined.

The cause of myopia is an over-refractive condition of the eye; either the cornea or the crystalline lens is too convex, or the humours of the eye generally are too dense or too abundant.

Treatment.—Although it is said that short-sightedness rarely comes on before puberty, our own observations lead us to believe that it is more frequently a congenital defect than is generally imagined. If, however, an incipient case were brought under the notice of the practitioner which could be shown to have followed too great an exercise of the eyes upon minute objects, the cure would probably be found in abstaining entirely for a time from such occupations, refraining also from the use of convex glasses, and employing the eyes chiefly upon large and distant objects. But this defect is one that is so little thought of, and is so easily remedied by the use of glasses, that a medical man is seldom called upon to attempt its cure: the only plausible means that have been recommended with this view are, practising the eyes in reading at gradually increasing distances, and a renunciation of such pursuits as require the concentration of vision upon near objects. The manner in which concave glasses improve the vision of near-sighted persons, is by causing a divergence of the rays of light before they enter the eye, thus counteracting the over-refractive condition of that organ. The glasses that are most commonly used are double concaves, of equal concavity on each side; they are numbered 1, 2, 3, 4, &c., beginning with the longest focus or shallowest concavity. Unfortunately there is no uniform standard adopted in the manufacture of these glasses, so that what one optician calls No. 1, another rates as No. 2, and so on; it is therefore advisable that those who wish to fit themselves with spectacles should try a series of them at an optician's shop, and they should be content with the lowest number with which they can see objects clearly across the street; if it diminishes them much, or gives them a dazzling appearance, or if the eyes feel strained after looking through them for a short time, they are too concave. Spectacles are always preferable to a single eyeglass; and when the individual has met with a pair which suit him, they should not be heedlessly changed for any of deeper concavity. It is also advisable not to wear them constantly, but only on occasions when their assistance is absolutely required.

Presbyopia, or *Far-sightedness* (from πρέσβυς, "old," and ὤψ, "eye;" this being a state of vision to which old age is almost invariably subject.)

Long-sightedness, as the name sufficiently indicates, is an affection the reverse of the one just described, and depends upon opposite causes. Either the refractive powers of the eye are too feeble, or its axis is shorter than is natural; the result is an imperfectly formed image on the retina, from the rays of light not converging sufficiently soon to be brought to a focus. Hence the far-sighted person removes the object he is examining farther from him, or he makes use of glasses whose effect is to increase the refraction of the rays of light before they enter his eye. Far-sightedness is sometimes met with in the young; but it is rare that an individual lives to be old without becoming presbyopic: indeed the sinking of the eyeballs, the flattening of the corneæ, and the smallness of the pupils, all which contribute to this effect, are among the series of changes which every part of our body undergoes as we advance in age. The time of life at which presbyopia first shows itself is generally about forty-five; but there are great differences in this respect, some persons requiring the use of convex glasses at thirty as much as others at fifty. Among the earliest symptoms observed, are a difficulty of reading small print, in nibbing a pen, or in examining small objects; the letters of a book appear misty, and run one into another; and if the effort is long continued, the eyes become fatigued and the head aches. Notwithstanding this difficulty of distinguishing near objects, distant ones continue to be seen as clearly as before.

Presbyopia, after it has once appeared, generally goes on increasing, so that an individual thus affected requires to change his glasses from time to time for those of a higher power: instances, however, are recorded of old persons long accustomed to the use of convex glasses recovering their former sight at the age of 80 or 90 years.

Treatment.—The same principles that we have laid down for the treatment of myopia, and for the use of concave glasses, are applicable, regard being had to the opposite condition of the eye, to the present affection. Convex glasses should not be had recourse to too soon, nor should too high a power be used, but the lowest that answers the purpose is to be chosen. When presbyopia occurs suddenly, and in an individual much below the age at which it ordinarily occurs, there is some mischief to be suspected either in the eye or in the brain, which will require an antiphlogistic treatment and a total suspension of the use of the eyes in regarding near or small objects.

Double Vision, *Visus duplicatus*, or *Diplopia*, may arise either from a want of correspondence in the movements or position of the two eyes, the vision of each eye singly being perfect; or there may be double vision with one eye only, while the harmony in the movements of the two is not disturbed. The most common example of the first form of the affection is afforded by cases of squinting; but as this defect is treated of in a separate article, we merely allude to it in this place. More serious and less common is the loss of harmony in the movements of the eyes which results from paralysis of one or more of the orbital muscles. If one muscle only is affected, the eye will move in harmony with its fellow in every direction but the one towards which its paralysed muscle should draw it, consequently in this direction objects will be seen double; but if several are affected, as is not unfrequently the case, then the movements of the eye will be still more restricted, and there will be single vision only when the axis of the sound eye is parallel with that of the paralysed one. These affections appear sometimes to arise from cold; at other times they are dependent upon disease about the base of the brain, as some tumour pressing on the motor oculi nerve, or there may be an inflammatory condition of the brain and its membranes, or a sanguineous or serous effusion involving the origin of the third pair of nerves. Whichever of these may be the cause, our treatment must be directed to remove it, while the state of the eye will be an index of the success or failure of the remedies we make use of.

Double vision with a single eye is a more rare affection than the one just described, and depends upon some irregular refraction of the cornea or lens.

M. Prévost, who published an account of his own case in the 'Annales de Chimie et de Physique,' 1832, thought it might arise from a fracture, bruise, or partial flattening of the lens, or separation of its laminæ. Professor Airy and Mr. Babbage are troubled with this defect, the latter gentleman with both eyes, but he is able to remedy it by looking through a small hole in a card, or through a concave lens. Professor Airy finds that his eye refracts the rays to a nearer focus in the vertical than in the horizontal plane, and he has ingeniously contrived to remedy it by the use of a double concave lens, one surface of which is spherical and the other cylindrical. The spherical surface is to correct the general defect of a too convex cornea; the cylindrical is to converge or diverge those rays at right angles to the axis, while the parallelism of those which impinge upon it in the plane of its axis is unaffected. Thus the focus of the spherical surface will remain unaltered in one plane, but in the other it will be changed to that of a lens formed by it and a spherical surface of equal curvature with the cylinder. With the aid of a glass of this description Professor Airy could read the smallest print at a considerable distance equally well with the defective as with the sound eye. He found that vision was most distinct when the glass was pretty close to the eye and the cylindrical surface turned from it. "With these precautions," he observes, "I find that the eye which I once feared would become quite useless, can be used in almost every respect as well as the other."

Colour Blindness; Dichromism; Chromatopseudopsis; Defect of the Sense of Colour; Daltonism.—There are some persons who, although they can see the size and form of objects perfectly well, have nevertheless a deficient power of distinguishing colour. Many distinguished individuals have been subject to this: such as Dugald Stewart, M. Sismondi, and John Dalton, the celebrated chemist. The subject first excited general attention by the latter distinguished individual having reported his own case, and the deficiency was hence called Daltonism. This subject was investigated by the late Dr. George Wilson, of Edinburgh, who has written a work on 'Colour Blindness' (1855), which contains by far the fullest account of this defect which exists. Dr. Wilson divides the colour-blind into three classes. 1. Inability to discern any colour properly so-called, so that black and white, that is, light and shade, are the only variations of tint perceived. 2. Inability to discriminate between the nicer shades of the more composite colours, such as browns, grays, and neutral tints. 3. Inability to distinguish between the primary colours—red, blue, and yellow; or between those and the secondary colours, such as green, purple, orange, brown. The last variety is the most common. In all these cases it would appear that the primary defect is the inability to distinguish the red colour, and the influence it exerts on the other colours of the spectrum. Dr. Wilson has narrated a large number of cases, and shown that this derangement of vision is much more common than has hitherto been supposed. He calculates from his own observations that at least one person in fifty is thus affected. Dr. Wilson has shown that it becomes very important to know where this defect exists, as it incapacitates people for occupations where the appreciation of colour is important. He has specially shown that, in cases of engine-drivers on railways and sailors at sea, who are warned of danger by coloured signals, this condition may lead to serious disasters.

The cause of this phenomenon has occasioned much discussion. Dalton attributed it to the condition of the humours of the eye; but a careful examination of his eyes after death, by Mr. Ransome, revealed nothing to account for the defect. It has been supposed by others that the defect is connected with the organisation of the brain. Recently Professor Clark Maxwell, of Cambridge, who has written a paper 'On the Compound Theory of Colours,' in the 'Philosophical Transactions' for 1860, explaining his views, has proposed another theory, which has been generally accepted. He has shown that the three primitive colours are not, as usually regarded, red, yellow, and blue, but red, green, and blue, as pointed out by Young. He has also adopted Young's theory that there is a distinct retinal structure for the perception of each colour, and shown how the remarkable defect of appreciation of the red rays occurs in the colour-blind. Professor Maxwell has also suggested the only means of alleviating this defect which has hitherto been recommended, and that is the wearing of spectacles composed of red and green glass simultaneously. A spectacle frame of the usual kind is constructed with one glass red, the other green, so that the right eye, for example, of the wearer of the spectacles looks always through red and the left always through green. Through the red glass red objects appear *brighter* than green ones, through the green glass green objects appear brighter than red ones, so that a colour-blind person puzzled between red and green has only to determine whether the doubtful colour appears brighter to the right or the left eye, and to set it down as the colour of the glass which brightens it. (See Maxwell 'On Colour as perceived by the Eye, with remarks on Colour-Blindness,' 'Trans. Roy. Soc. Edin.,' 1854–5, vol. xxi. part ii.)

SIGN (Astronomy), a constellation; but in modern times a constellation of the ZODIAC only. For the distinction of the sidereal and astronomical zodiac, see PRECESSION.

SIGN (Mathematics). Every symbol is a sign of something or other, the original meaning of the word applying to any mark of distinction or designation. The general consideration of the subject of signs comes under the word SYMBOL; for this term, sign, is exclusively applied in mathematical analysis to the signs of addition and subtraction (+ and −). A positive quantity, as +3, is said to have the positive sign; a negative quantity, as −3, the negative sign.

The theory of these signs is the peculiar feature of ALGEBRA, as distinguished from arithmetic; and it is difficult to place it on any satisfactory basis except that of distinct definitions not wholly derived from arithmetic. On this point, however, it is not our present purpose to enter further; the object of this article being the application of the signs, and in particular those details of interpretation which are necessary in the application of ordinary algebra to geometry. By ordinary algebra we mean that system in which the positive and negative quantities are fully capable of interpretation, but in which $\sqrt{-1}$ is considered as incapable of interpretation.

The relative meaning of + and − is direct opposition of properties; and it is only where direct opposition is possible that complete interpretation can exist. The symbol +7 means not only 7 units of its kind, but 7 units directed to be considered in a specific one of two (the only possible) lights, or used in a specific one of two (the only possible) manners; the first generally implying the second. Thus let 7 inches be measured from a given point; the superposition of + or − tells nothing, for the measurement may be made in an infinite number of different directions. Choose one of these directions, or rather one line of direction, and the indeterminate character of the proposal (to measure seven inches from the given point) is almost gone: there are but two directions in which to do it; if one of them (no matter which) be signified by +7, the other (no matter which, except with reference to the first) must be denoted by −7.

A problem may present different sets of oppositions of very different kinds. Thus we might have a problem in which there are concerned together—1, time before or time after a certain epoch; 2, height above or height below a certain level; 3, the debtor or creditor side of certain books. To give a more precise idea (it is hardly worth while to frame a specific problem), a man might engage to build a wall on different terms as to the foundation and what is above the ground; for which he might have to borrow money and pay interest up to a certain time, when by receiving the whole amount due to him he might repay and invest besides; and the whole transaction might have to be properly entered in his books. The young student might suppose that if + 1 and −1 represent a foot of the wall above and a foot below the ground, it will not necessarily follow that + 1 and − 1 (undistinguishable from the former) will do to represent one pound of interest due to and from the contractor; and still less that the same + 1 and − 1 will also do to direct 1*l.* to be carried to the debtor or creditor side of his books. But what he will learn from a properly established algebra (and until he has learnt it, he is not in possession of any part of the difference between algebra and arithmetic) is this—that he would gain absolutely nothing by inventing such distinctive symbols as would remove his doubt of their applicability. Let (+)1 and (−)1 represent feet of wall, [+]1 and [−]1 pounds sterling of interest, {+}1 and {−}1 pounds sterling carried to one side or the other of the books; while + 1 and − 1 represent simple addition or subtraction. Let the problem be fairly translated into algebraical language, and an equation formed in which all the distinctive symbols are seen: algebra teaches that the rules to be applied to that equation differ in no respect whatever from those which would have been applicable if all the signs had come from the same source of meaning. Perhaps it would be better if the student were not allowed to come so easily by this result as he usually does, but should be made to learn by his trouble how unnecessary the distinctions really are, as to operations, and allowed in due time to feel the relief afforded by dropping them.

When a problem admits of but one opposition (say it simply refers to time measured future or past from a given epoch), there is no difficulty about the interpretation of any result. If this result be positive, it must be such time as was called positive when the operation was put into shape; and the contrary. But in the application to geometry, an extension of the interpretation of signs enables us to remove some difficulties in the proper expression of angles, which we proceed to describe.

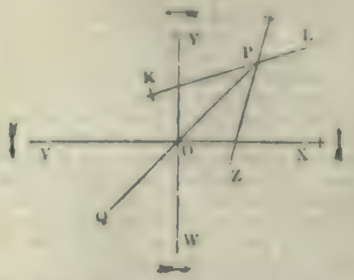
In the rectilinear figures considered by Euclid the sum of the external angles is always equal to four right angles. In these figures there are no re-entering angles. [SALIENT.] The proposition remains true when there are re-entering angles, provided that the angles which then take the place of what were called *external* angles be counted as negative. In algebraic geometry it is usual to refer all points and lines to two straight lines at right angles to one another. [ABSCISSA; CO-ORDINATES.] The following conventions must now be employed:—

1. Let VX and WY be the axes of co-ordinates, meeting at O, the origin. Let OX and OY be positive directions: OV and OW, negative directions.

2. A line drawn from O to any point P is in itself (for the present) neither positive nor negative; either sign may be given to OP, but the contrary one must be given to OQ.

3. The line OP may, keeping its sign, revolve round O; nor, if negative, is it to be counted positive when it comes into momentary coincidence with OX; nor, if positive, is it to be counted negative when in coincidence with OV. And generally, a straight line revolving round any point does not take the signs of lines which receive signs on account of the fixed directions in which they are drawn.

4. The angle made by two lines A and B is to have a distinction of sign drawn, according as it is called the angle made by A with B, or the angle made by B with A (the angles made by A *from* B, and by B *from* A, would be better). If the angle of A with B (say A^B) be positive, then the angle made by B with A (B^A) is negative, and *vice versâ*.



5. The positive direction of revolution is that in which a line moves from the positive part of the axis of x to the positive part of the axis of y (as marked by the arrows).

6. The sign of any line drawn through P is thus determined. If OP be *positive*, that direction is positive in which the point P must move so as to revolve *positively*; thus, OP being positive, PK is positive and PL negative. But if OP be negative, the reverse is the case; but the rules need only be remembered which suppose OP positive.

7. When an angle amounts to more than four right angles, the four right angles may be thrown away; and generally, four right angles, or any multiple of them, may be added to or subtracted from any angle.

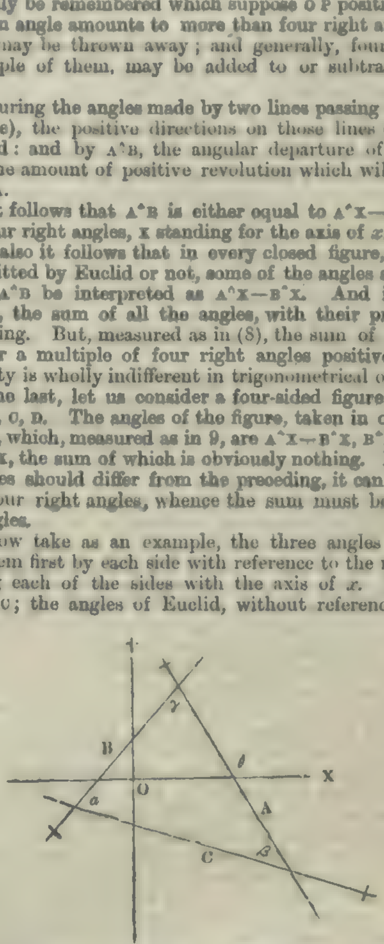
8. In measuring the angles made by two lines passing through P (OP being positive), the positive directions on those lines (found as in 6) must be used: and by A^B, the angular departure of A from B, is understood the amount of positive revolution which will bring B into the position A.

9. Hence it follows that A^B is either equal to A^X−B^X, or differs from it by four right angles, X standing for the axis of x.

10. Hence also it follows that in every closed figure, whether such as those admitted by Euclid or not, some of the angles are negative, if every angle A^B be interpreted as A^X−B^X. And in every such measurement, the sum of all the angles, with their proper signs, is equal to nothing. But, measured as in (8), the sum of all the angles is nothing, or a multiple of four right angles positive or negative. This ambiguity is wholly indifferent in trigonometrical operations.

To prove the last, let us consider a four-sided figure, of which the sides are A, B, C, D. The angles of the figure, taken in order, are A^B, B^C, C^D, D^A, which, measured as in 9, are A^X−B^X, B^X−CX, ^C^X−D^X, D^X−A^X, the sum of which is obviously nothing. But if any one of these angles should differ from the preceding, it can be only by a multiple of four right angles, whence the sum must be a multiple of four right angles.

We shall now take as an example, the three angles of a triangle, estimating them first by each side with reference to the next, and then by comparing each of the sides with the axis of x. The sides are marked A, B, C; the angles of Euclid, without reference to sign, are



α, β, γ: and the positive and negative directions are marked. Four right angles are denoted as usual by 2π. Required A^B + B^C + C^A.

In A^B, the amount of positive revolution by which the positive part of B turns round into that of A is $\gamma+\pi$. Similarly for B^C, we have $\alpha+\pi$, and for C^A, $\beta+\pi$. The sum of these, $\alpha+\beta+\gamma$ being π, is 4π, a multiple of 2π. Now let the angle A^X be θ. Then B^X will be seen to be an angle in this figure greater than two right angles, and will be found to be $\pi+\theta-\gamma$, while C^X is greater than three right angles, and is $2\pi-\alpha+\theta-\gamma$. Hence we have

$$\begin{aligned}
\mathrm{A}\,\hat{}\,\mathrm{B} &= \theta-(\pi+\theta-\gamma)=\gamma-\pi\\
\mathrm{B}\,\hat{}\,\mathrm{C} &= \pi+\theta-\gamma-(2\pi-\alpha+\theta-\gamma)=\alpha-\pi\\
\mathrm{C}\,\hat{}\,\mathrm{A} &= (2\pi-\alpha+\theta-\gamma)-\theta \qquad\quad =\beta+\pi.
\end{aligned}$$

Only the third angle gives precisely the same in both; in the other two, the second determination gives in each case four right angles less than the first. The sum of the three angles is now 0.

The use of this system lies in enabling us to give in a general form propositions which would otherwise require a large examination of particular cases. This examination is not usually made in elementary works; but instead of it, the true result, derived from the superior knowledge of the writer, is made to the reader the consequence of a particular case. In the consideration of curves, for instance, there are to be considered, perhaps at the same time, the co-ordinates, the radius vector, the tangent, the perpendicular on it, and the radius of curvature. The varieties of figure which arise out of these lines are very numerous, and nothing but generalised suppositions, competent to assign definite angles in all cases, can legitimately bring out general propositions. For instances, see TANGENT, SPIRAL; and for further development, see 'Library of Useful Knowledge,' Differential Calculus, pp. 341-345.

SIGN-MANUAL means, in its widest sense, the signature or mark made by a person upon any legal instrument to show his concurrence in it. Before the art of writing was so universally practised as it now is, the sign-manual or signature was usually a cross, attested either by the seal of the party containing his armorial bearings, or by the signature of another person declaring to whom the mark belonged. The latter indeed is still the practice with persons who cannot write.

Sign-manual now however is used to denote the signature of a reigning prince. It is usually in this country the prince's name, or its initial letter, with the initial of his style or title in Latin. Thus the sign-manual of George IV., when prince regent, was George P. R., or G. P. R.; that of the present queen is Victoria R., or V. R.

The royal sign-manual is usually placed at the top left-hand corner of the instrument, together with the privy seal; and it is requisite in all cases where the privy seal and afterwards the great seal are used. The sign-manual must be countersigned by a principal secretary of state, or by the lords of the treasury, when attached to a grant or warrant, it being then the principal act, and it must also be accompanied by the signet or privy seal. But where the sign-manual only directs that another act shall be done, as for letters-patent to be made, it must be countersigned by some person, though not necessarily by these great officers of state. The authenticity of the sign-manual is admitted in courts of law upon production of the instrument to which it is attached. (Comyn's 'Digest.')

SIGNATURE, in Music, is the term by which the clefs and sharps or flats placed at the beginning of each staff are, collectively, known, and by which the key is partly shown. See KEY, where the *Signature* in every key is given.

SIGNATURE, in Printing, is the name given to the letters or figures which are placed at the bottom of certain pages in each sheet of a book, to facilitate the gathering, folding, collating, and binding of it. The French printers generally use figures, but English printers for the most part use small capital letters. The bookbinders' alphabet, as it is called, contains only 23 letters (*j*, *v*, and *w* being omitted); and as the title-sheet, which contains the dedication, preface, &c., is generally printed last, the signatures of the work itself commence with B, leaving A for the title sheet. If there be other introductory matter besides the title-sheet, small letters, as a, b, &c., are used till the work itself is reached. If the work contain more than 23 sheets, the second set of signatures are AA, BB, or more commonly 2 A, 2 B, &c.; and the third set 3 A, 3 B, and so on. If the work is in folio it requires only one signature; if in 4to or 8vo, it requires two, as, for instance, B on the first page and B 2 on the third; if in 12mo, it requires three, as B on the first page, B 2 on the third page, and B 3 on the ninth page; and so on for printed works of other forms.

SIGNET, SEAL. The law recognises three royal seals:—1, The great seal, which is in the custody of the lord chancellor: this is appended to all letters-patent, and contains two impressions, the one being usually the sovereign on horseback, the other the sovereign seated, supported by emblematical figures, and with the coat of arms somewhere in the field. The great seal is essential to all royal grants of inheritances or chattels real, to grants of an office in fee, and to all writs at common law. Where the king's seal is mentioned, it is understood to be the great seal. 2. The privy seal, which is in the custody of the lord keeper of the privy seal. This seal is valid for the issuing of the royal treasure, or for disposing of chattels, or the contracting or discharging of a debt. It is used as a warrant for letters-patent before they pass the great seal. The privy seal consists of the arms of the sovereign. 3, The signet, or privy signet, which is in the custody of the principal secretaries of state. Except that it authenticates the sign manual, this seal seems to have no validity, although it is alleged to be sufficient to give validity to the writ *ne exeat regno*, whereby a subject is prohibited from going out of the realm. For the use of all the seals the countersignature of a principal secretary of state is required by statute. [SEAL.]

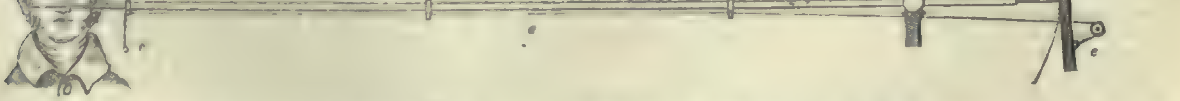
SILE'NUS (Σειληνός), a Greek deity. The traditions of his birth are various: he is said to be the son of Pan and of a nymph; of Gæa; and to have sprung from the blood of Uranus. He was the instructor and constant associate of Dionysos; was a lawgiver and prophet, sometimes confounded with Dionysos himself; of the family of Satyrs, whom he resembled very much in appearance and habits. He is represented as an old unwieldy man, bald, with a beard, and depressed nose, sometimes with a tail; at times holding the infant Bacchus in his arms; sitting astride a wine-skin, or carrying one on his shoulders. He has a conspicuous place in the Dionysian processions, and occurs in various combination with fauns and nymphs; sometimes he rides on an ass reeling and supported by a satyr; and sometimes he is carried by youthful satyrs. Though endowed with supernatural wisdom, he is of a jovial disposition; his whole character is a mixture of jest and earnest; he is harmless, sportive, fond of children; addicted to wine; is said to have conducted Dionysos from Thrace to Phrygia; and to have been ensnared by Midas in a garden, and compelled to exert his marvellous power of speech. His discourse, always ironical, was of the second world, of the land of Meropis, and of its strange men, beasts, and plants, of the origin of things and birth of the gods, and he showed the miserable condition of this present life. The ass by which he is accompanied has given rise to many conjectures; the Dionysian myths and those of Apollo speak of this animal as sacred to both deities. It may therefore be considered as the link uniting the two worships; and we find accordingly Apollo called the son of Silenus. (Porphyry, 'Vit. Pythag.,' p. 10, ed. Rome, 1630.) Attempts have been made by Bochart and others to connect Silenus with the name Shiloh in Scripture, and his ass with that of Balaam. Other imaginary resemblances are noticed by Creuzer ('Symbolik'), founded on the theory that the ass is the symbol of prophecy in the East.

The distinction between Sileni and Satyrs appears to be that the Sileni are the older of the two. The terms were certainly not co-extensive; that of Satyr may be considered as the genus; but they are represented much in the same manner. See, for representations of Silenus, Creuzer's 'Symbolik,' Grüber's 'Wörterbuch der Mythologie,' and Müller's 'Denkmäler der Alten Kunst' (Nos. 494-522); Millin's 'Galérie Mythologique,' and the various works on gems, sculpture, vases, and other monuments of classical antiquity.

SILEX. [SILICON.]

SILHOUETTE, a name applied to the black profile portraits, commonly known simply as *profiles* or *shades*. The latter name indicates the origin of this simple class of pictorial representations, they having been probably suggested by the shadow thrown upon a wall. The name *silhouette* has been said to be derived from Etienne de Silhouette, French minister of finance in 1759. It appears that several parsimonious fashions introduced during his administration, in order, by severe economy, to remedy the evils of a war that had just terminated, were called, after this minister, *à la Silhouette*, and that the name has continued to be applied to one of them—the use of profiles in shade.

Silhouettes are executed in various ways. One of the simplest is that of tracing the outlines of a shadow thrown on a sheet of paper, and then reducing them to the required size, either by the eye or by means of a pantograph. [PANTOGRAPH.] The camera-obscura and camera-lucida are also occasionally used for the purpose. A more certain mode of obtaining an accurate outline is by the use of the machine invented for the purpose by Mr. Schmalcalder, and patented by him in 1806. The principle of this machine is very simple, and may be readily understood by the aid of the annexed diagram. *a b* is an inflexible rod, usually about nine or ten feet long, supported by a ball-and-socket joint at *c*, in such a manner as to leave the ends free to move in any direction. At the end *a*, a *tracer*, which is tapered off to a fine point, is attached to the rod, so as to form a continuation of it; while at the opposite end, *b*, a steel point is similarly fixed. The person whose profile is required is seated, in the position indicated in the cut, in a chair having a rest for the back of the head, in order that he may sit perfectly still, while the operator gently passes the side of the tracer, *a*, over his features. By the intervention of the universal joint (or of a double-swivel joint) at *c*, a perfectly similar motion is communicated to the steel point at *b*, although, owing to the pivot being placed nearer to it than to the other end of the rod, it moves in a path smaller than that of the tracer *a*. The pivot *c* being stationary, the steel point at *b* moves in the arc of a circle of which it (the pivot) is the centre, as indicated by the dotted line in the diagram; and therefore, in order to keep the paper always in contact with it, it is fixed on a swinging board, pivoted at *d*, and constantly pressed against the steel point by means of a weight or spring, with a sufficient degree of force



to make it act efficiently. The steel point does not come into immediate contact with the white paper, but with a piece of blacked paper placed over it, the pressure of the point transferring a sufficient quantity of the colour to form a distinct line. This part of the operation resembles that of a manifold writer; and, as in that instrument, several copies may be produced simultaneously, by using a number of pieces of white and blacked paper, laid alternately upon the swinging board. The size of the reduced outline drawn on the paper may be regulated by varying the relative proportions of *a c* and *c b*; this and several other adjustments being effected by apparatus which it is unnecessary here to detail. By means of a cord, *c c c*, held in the hand of the operator, the swinging board *d* may be drawn back from the steel point when it is required to move the rod without making a mark upon the paper. Greater accuracy may be attained by substituting for the tracer a thin wire, tightly stretched in a bow, and adjusted so as to coincide perfectly with the axis of the rod. In some cases a kind of knife is substituted for the steel point at *b*, and the profile is thus cut out of a piece of thin black paper placed on the swinging board. Some profilists display considerable talent in cutting silhouettes by hand, with a pair of scissors, out of pieces of black paper, without the assistance of an outline.

SILICA. [SILICON.]

SILICIC ACID. [SILICON.]

SILICIUM. [SILICON.]

SILICOFLUORIC ACID. [SILICON.]

SILICON (Si). *Silicium.* With the exception of oxygen, silicon is the most abundant constituent of our earth's crust. Its name is derived from *silex*, Latin for "flint," of which the essential component is silicon. The element silicon has great affinities for other elements, and hence does not exist, in nature, in the free state. Its common, and apparently sole, native form of combination is an oxide known as *silex* or *silica.* Rock crystal and white quartz are nearly pure varieties of silica; while calcedony, agate, opal, flint, and sand are chiefly silica. The natural compounds of silica with oxides are almost innumerable. The individuality of siliceous minerals was recognised at a very early period, but their constitution was not demonstrated till the commencement of the present century.

Silicon itself was first isolated only so lately as 1823. It may be prepared by reducing an alkaline silico-fluoride with potassium, in a glass or iron tube, at a high temperature. It may also be obtained by passing chloride of silicon vapour over potassium heated in a bulbed glass tube.

Silicon, like CARBON and BORON, exists in three distinct modifications. As above prepared, it is a dull-brown powder; insoluble in, and heavier than, water; is a non-conductor of electricity, is soluble in hydrofluoric acid, and in a warm solution of potash; burns readily and brilliantly when heated in the air; and is moreover *amorphous* (Siγ). If the amorphous silicon be strongly heated it becomes semicrystalline or *graphitoidal* (Siβ); is denser and darker in colour; does not burn in oxygen: is not soluble in hydrofluoric acid; and is a conductor of electricity. *Crystalline* silicon (Siα) occurs in the form of six-sided prisms or pyramids, whenever the process for its preparation has included the application of the most intense heat of a wind furnace.

The equivalent of silicon has, in turn, been represented as 7, 14, 21, and 28; but since the experiments of Marignac, who proved that the fluo-stannates and fluo-silicates are isomorphous, it has been usual to consider the number 14 as the true equivalent of silicon.

Silicon and *oxygen* form two compounds:—

1. Hydrated protoxide of silicon . .	$2HO, 3SiO$
2. Silicic acid	SiO_2

1. *Hydrated protoxide of silicon* ($2HO, 3SiO$).—When dry hydrochloric acid gas is passed over crystallised silicon, heated to incipient redness, hydrochlorate of protochloride of silicon ($2HCl, 3SiCl$) is produced, and may be condensed to the liquid state in a U-tube cooled by ice; hydrogen passes off carrying vapour of protochloride with it; the gas being allowed to bubble through water the chloride is decomposed, and a voluminous white precipitate of the oxide under consideration is formed:—

$$2HCl, 3SiCl + 5HO = 2HO, 3SiO + 5HCl.$$

Hydrated protoxide of silicon sinks in water but floats on ether; the caustic alkalies and their carbonates dissolve it with evolution of hydrogen and formation of silicate; it may be heated to 570° Fahr., without undergoing alteration, but at a higher temperature burns; and in contact with water undergoes oxidation, hydrogen being evolved, at any temperature above 32° Fahr.

2. *Silicic acid* (SiO_2), *Silex, Silica, Binoxide of silicon.*—The physical and chemical properties of the many different forms of silica that occur in nature, as well as a list of the minerals in which silica is a characteristic constituent, have already been treated of in the NATURAL HISTORY DIVISION of this Cyclopædia, article SILICA.

Silicic acid is largely used in the manufacture of glass, chinaware, and porcelain. For these purposes it is obtained in a fine state of division by igniting flints or colourless quartz to redness, and then plunging in cold water. The compact silica is thus split up into a friable mass, easily reducible to powder by grinding. Perfectly pure silicic acid may be obtained by igniting hydrated silica.

Hydrates of silicic acid (xHO, SiO_2).—Finely powdered silica is soluble in strong alkaline solutions if heated with them under pressure; from the resulting solutions hydrated silica is precipitated in a very gelatinous state on neutralising by hydrochloric acid. The alkaline silicate may also be formed by fusing powdered flint, &c., with the carbonates of potash or soda; if excess of the latter be used, the silicate is soluble in water, and the solution furnishes hydrated silicic acid on the addition of hydrochloric acid. Perfectly pure hydrated silica is formed in a very beautiful manner on passing gaseous fluoride of silicon into water, each bubble of gas forming a little balloon of silica; hydrofluosilicic acid (HF, SiF_2) is also formed at the same time, and remains dissolved in the water:—

$$\underbrace{3SiF_2}_{\text{Fluoride of silicon.}} + \underbrace{4HO}_{\text{Water.}} = \underbrace{2HO, SiO_2}_{\text{Hydrated silicic acid.}} + \underbrace{2(HF, SiF_2)}_{\text{Hydrofluosilicic acid.}}$$

Isomeric conditions of silica.—Professor Rose has recently directed attention to the two different states in which silica exists. Crystallised silica—including rock-crystal, quartz, calcedony, flint, sandstone, and quartzose sand—has a specific gravity, of about 2·9, and is only attacked with difficulty by potash, or hydrofluoric acid. Amorphous silica, on the other hand,—including gelatinous silica, the pulverulent variety that results from the decomposition of certain minerals, or of fluoride of silicon by water, opals, melted quartz, and silica from the carapaces of infusoria—is very readily soluble in alkaline solutions, is rapidly acted upon by hydrofluoric acid, and has a specific gravity of 2·2.

Silicates, as a general rule, are insoluble in water. Alkaline silicates are however, soluble in that liquid, and their solutions have lately been used as a varnish for the stonework of buildings with the view of preventing decay. When thus exposed to the atmosphere, the silica, being but a weak acid, is replaced by carbonic acid; the alkaline carbonate is removed by rain, and silicic acid filling up the pores of the stone is supposed to prevent ingress of moisture or other disintegrating matter. The fact is, however, that the decomposition alluded to, being but a slow one, a large portion of the silicate is washed away by the rain, and this process is consequently of but little value. A modification of the method, known as "Ransome's patent," consists in supplementing the application of the alkaline silicate by a wash of chloride of calcium; silicate of lime is hereby at once produced, and performs the office of a permanent varnish or cement, in a far more efficient manner than the mere silica before alluded to. Clay, talc, felspar, serpentine, mica, zeolites, hornblende, and many other minerals, consist of, or contain, silicates of lime, or magnesia, or alumina, or a mixture of those silicates. They are either *sesquisilicates* like meerschaum ($2MgO, 3SiO_2 + 2HO$), or *neutral silicates*, like Wollastonite (CaO, SiO_2); or *dibasic silicates*, like olivine ($2(Mg, Fe)O, SiO_2$); or *bisilicates* ($MO, 2SiO_2$). [SILICA, in NAT. HIST. DIV.]

Silicon and *hydrogen* form a *hydride of silicon.* Berzelius first showed that the hydrogen which is evolved when crude silicon is washed with water, contains a hydride of silicon. This gas has not yet been procured in a pure state, but, according to Wöhler and Buff, it is colourless and spontaneously inflammable. It occurs in the latter condition when a solution of a chloride is electrotised by a weak voltaic battery of which the positive pole is aluminium contaminated with silicon.

Nitride of silicon is a bluish, fibrous-looking body, formed when silicon is heated in nitrogen gas.

Sulphide of silicon (SiS_2).—Silicon burns in sulphur vapour, generating bisulphide. The same body may be formed on passing bisulphide of carbon over a heated mixture of carbon and silica. It is a white, earthy-looking powder.

Bromide of silicon may be obtained, but *iodide* does not seem to exist.

Silicon and *chlorine* form two compounds corresponding to the two oxides.

1. *Hydrochlorate of protochloride of silicon* ($2HCl, 3SiCl$).—The method of preparing this body has already been described in connection with protoxide of silicon. It is a colourless liquid, refracting light powerfully; emits suffocating fumes on exposure to air; is inflammable, burning with a pale green flame; and is decomposed at a red heat.

2. *Chloride of silicon* ($SiCl_2$), or rather, *bichloride* of silicon.—Finely powdered silica is made into a dough-like mass with lampblack and oil, and heated to redness in a covered crucible; a porcelain tube filled with fragments of the resulting mass is strongly ignited and a current of dry chlorine passed through it; the following decomposition occurs:—

$$\underbrace{SiO_2}_{\text{Silica.}} + \underbrace{Cl_2}_{\text{Chlorine.}} + \underbrace{C_2}_{\text{Carbon.}} = \underbrace{2(CO)}_{\text{Carbonic oxide.}} + \underbrace{SiCl_2}_{\text{Bichloride of silicon.}}$$

The chloride of silicon vapour must be condensed by the aid of a freezing mixture, for it is very volatile. It is a transparent, colourless liquid; fumes in the air, and has an irritating odour.

Chlorosulphides of silicon ($SiS_2, 2SiCl_2$) and ($2SiS_2, SiCl_2$) may be formed by the reaction of chloride of silicon vapour and dry hydrosulphuric acid gas at a red heat.

Fluoride of silicon (SiF_2) or *fluosilicic acid*, and *silicofluoric* or *hydrofluosilicic acid* (HF, SiF_2) have been described under FLUORINE.

Detection of silicon.—The presence of this element in such a substance as glass, or any transparent mineral, is readily demonstrated by the etching action of hydrofluoric acid. From solution it is precipitated as gelatinous silica on the addition of hydrochloric acid. Silica may also be individualised from its property of being after ignition insoluble in all acids, except hydrofluoric, but soluble in fused caustic alkali.

Estimation of silicon.—This is always performed in the state of recently dried and anhydrous silica, which contains 46·7 per cent of silicon, and 53·3 of oxygen.

SILK MANUFACTURE. This subject naturally divides itself into four parts:—The rearing of the insect which yields the silk; the extrication of the filament in a state fitted for the manufacturer; the spinning and weaving into textile fabrics; and the commercial arrangements arising out of the manufacture. Such portions of the subject will be treated here as have not yet been noticed in the Cyclopædia; for the rest, cross-references will suffice.

Rearing silk-worms.—Silk is produced by a small insect, in the manner described in BOMBYCIDÆ, NAT. HIST. DIV. China was undoubtedly the country in which men first availed themselves of the labours of the silk-worm. Serica (the country of the Seres) was a name by which the Macedonian Greeks designated the country which produced the silk that came overland from the north of China. The author of the 'Periplus of the Erythræan Sea' speaks of silk in Malabar as an article imported from countries farther to the east; from which it may be inferred that the culture of the silk-worm and the manufacture of silk had not been introduced even into India four hundred years after silk was known in Europe. In speaking of the country of the Thinæ, the same author observes that both the raw material and manufactured article were obtained there. The "Median robes," spoken of by the Greek writers of the period of the Persian empire, and extolled for their lustrous beauty and brilliancy, were no doubt silken vestments; as Procopius long afterwards, when silk had been introduced into Europe, states that "the robes which were formerly called Median by the Greeks are now called silken." Aristotle is the first Greek author who mentions the silk-worm ('Nat. Hist.,' v. 19). He states that silk was first spun in the island of Cos, but that the raw material was still an oriental product; and Pliny (xi. 22), in commenting on this passage, states that the silk came from Assyria, and was worked up by the Greek women. It may be remarked that Assyria was, like Media, frequently used in an indefinite sense by ancient writers. The probability is that silk was used in Western Asia before it was known to the Greeks; and that it was in use among the Greeks long before they knew whence the substance came or how it was produced.

Pausanias is perhaps the first who gives precise information respecting the substance from which the Seres formed their cloths. "They have," he says, "a spinning insect, which is kept in buildings, and produces a fine-spun thread, which is wrapped about its feet" (vi. 26). It was not until the sixth century that the obscurity which enveloped this subject was cleared up. At this time silk was an article of general use among the Romans, and was manufactured for them by the inhabitants of Tyre and Berytus in Phœnicia. The Persians monopolised the supply of the raw material, and guarded their trade with so much jealousy, both by land and sea, that travellers from or to China were not allowed to traverse the Persian dominions; and in the time of Justinian, in consequence of some interference with the trade, they had entirely stopped the importation of silk. The trade in silk was in this unsatisfactory state, when two Nestorian monks of Persia, who had travelled to China, acquainted Justinian with the mode of producing silk, and undertook to return and bring back with them some of the eggs of the silk-worm. They were perfectly successful in their expedition; for a quantity of eggs, secured in a hollow cane, were brought in safety to Constantinople, hatched by the heat of a dunghill, and fed with mulberry-leaves. The monks also taught the subjects of Justinian the art of manufacturing silk.

The breeding of silk-worms in Europe was for six centuries confined to the Greeks of the Lower Empire. In the 12th century the art was transferred to Sicily; in the 13th century the rearing of silk-worms and the manufacture of silk were introduced into Italy, and from thence successively introduced into Spain and France.

James I. was solicitous to promote the breeding and rearing of silk-worms in England; and in 1608 issued circular letters, which were addressed to persons of influence throughout the country, recommending the subject to them; but the experiment was unsuccessful. Most of the old mulberry trees found in the neighbourhood of ancient mansions in England at the present day were planted at this period. The experiment has also failed, though several times attempted, in North America.

The production of raw silk is fast extending in British India, and the quality has been for some years gradually improving. In Graham's 'India,' it is said that in the Deccan the mulberry-trees may be deprived of their leaves six times a year, and that six crops of worms may be obtained with ease in the same period. The Chinese method of rearing silk-worms, and their mode of treating the mulberry-tree (described in Davis's 'China,' p. 280), were introduced at St. Helena, under the auspices of the East India Company; but on the expiration of their charter the establishment was given up. Some of the silk produced in France is believed to be better than that of any other country in the world. The Italian silk is also highly esteemed.

There has recently been a very earnest attempt made to disseminate the silk-worm culture in various parts of Europe. In 1854 some silk-worm eggs, reared at Assam, were brought from Calcutta to Malta, through the aid of Mr. Piddington. They were not the usual kind, but a variety called the *Bombyx cynthia*, which feeds on the castor-oil plant. Sir William Reid, Governor of Malta, caused these eggs to be carefully tended; 500 of them were hatched, and fed on the castor-oil plant. After some time, portions of the store were sent to Piedmont, France, Algiers, and the West Indies, in order that fair trials might be made in different climates. It is known that the castor-oil plant suffices to give the worms the silk-producing power; for the Assamese make shawls, dhoties, coverlets, coats, turbans, and women's dresses, with silk thus obtained. Early in 1855 it was found that the worms at Malta declined and died off, from some cause not clearly traceable; and the attempt failed, so far as that island was concerned. In 1856, however, some of the eggs reached Prussia; and great endeavours are now being made to foster the culture in Germany, Sweden, and Russia. The silk produced by this kind of worm is not so fine as the mulberry-silk; but is believed to be more easily worked, if the insect can only be made to thrive. As to England, silk-worm rearing has been to the present day, and still is, nothing more than an amusement, or an experiment having no commercial value.

This may be the proper place to say a few words concerning other filaments of the nature of silk. The web of many kinds of caterpillars has been found nearly equal to silk, and gloves and stockings have been made of it; but Reäumur found that 50,000 of the insects were needed to yield 1 lb. of silk, and, moreover, that the caterpillars showed a very unprofitable tendency to kill and eat each other. Some fabrics exquisitely light, others moderately strong, have been made from caterpillar filament, but hitherto without commercial success. The *pinna*, a gigantic kind of mussel found in the Mediterranean and the Indian Ocean, fastens itself to rocks with a kind of cord made of beautiful silky filaments; these filaments may be worked up in the manner of silk; but the supply is too small to render the matter other than a curiosity. Very recently there was landed at Liverpool a small quantity of *pulu* or vegetable silk, obtained from the lower part of the stalk of a fern growing in Sumatra; the stalk is covered with a kind of sparkling golden-brown hair, which can be detached and worked up as silk. About 3 ounces can be obtained from each plant. The substance has not yet attracted much attention in England, but is beginning to be worked in America.

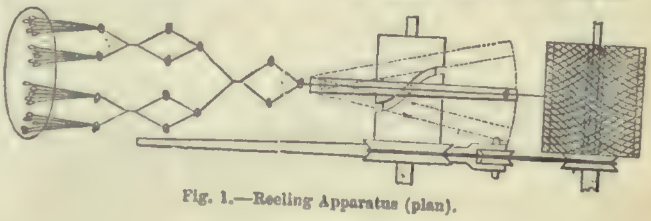


Fig. 1.—Reeling Apparatus (plan).

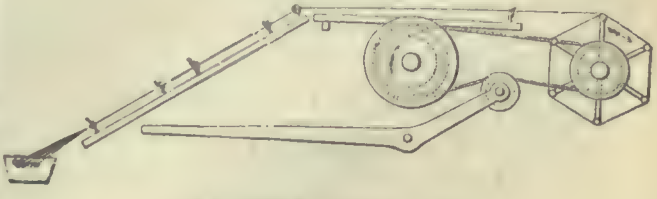

Fig. 2.—Reeling Apparatus (section).

The Cocoons and Silk Reeling.—The cocoons [BOMBYCIDÆ, in NAT. HIST. DIV.] average in weight about 3 grains each; the average length of silk upon each, when reeled off, is about 300 yards; and 12 lbs. of cocoons are required to yield 1 lb. of reeled silk—so many are the impurities to be got rid of. About 1 ounce of silk-worm eggs will produce 100 lbs. of cocoons; 16 lbs. of mulberry leaves will afford food sufficient for the production of 1 lb. of cocoons; and each mulberry tree will yield about 100 lbs. of leaves. These figures will afford easy means of calculating the number of insects, eggs, trees, leaves, &c., necessary for the production of 6,000,000 or 8,000,000 lbs. of silk—about the annual consumption of the United Kingdom. *Reeling*, or the drawing off of the silken filament from the cocoon, is usually done only in the countries where the worm is reared. To effect this, the worm is not allowed to die a natural death; the cocoon is exposed to the heat of the sun or of an oven until the insect is stifled. An external soft envelope is removed, constituting *floss silk*; the real silk is wound closely around the cocoon, in an agglutinated mass. The cocoons are steeped in hot water until the gum is dissolved. The reeler (a woman or girl), with a kind of whisk or brush, detaches the ends of ten or twenty filaments from as many cocoons, winds them two or three together on a reel, then two or three of these groups together, and so on until all form one thread, very much thicker than the original filament, but still exceedingly fine. New cocoons are thrown into the vessel of hot water as fast as the old ones are exhausted, so that the thread is made continuous; and the temperature of the water is such as will enable the cocoons to give off the filaments just as fast as the reeler can wind them. In some districts the reeling is done in a quicker and better way, by aid of the apparatus shown in *fig.* 1 (plan), and *fig.* 2 (section). From the reel the silk is made up into *hanks*, which present different appearances, according to the countries whence they are obtained. Broussa and China hanks are whiter than the others; Bengal hanks are small; Italian are larger; and Persian are the largest and coarsest of all.

Such is the simple operation of reeling. It has been a conventional opinion that this can only be done in the silk rearing countries; because the cocoons cannot be conveyed long distances safely, and because a clear and warm climate is necessary. The correctness of this opinion is now disputed. Mr. Dickins, a silk dyer at Middleton, and Mr. Chadwick, a silk manufacturer at Manchester, have invented and set to work a system of apparatus for reeling silk in England, and throwing or twisting the silk so reeled. The cocoons are placed for a few minutes in hot soap and water; and then ladled to a trough of clean warm water. The principal end of the silk of each cocoon is drawn out by the fingers; several cocoons, thus treated, are placed in a basin, with the ends of the filaments hanging over the edge; and they are thus taken to the reeling frame when wanted. The machine consists of an iron framework, 12 feet long, 4 feet wide, and 4 feet high. At each side is a row of 30 bobbins, each with a flyer, and with a separate rotary motion. Over the 60 bobbins are 60 copper basins, containing water at 120° Fahr. Into each basin are put 6 cocoons, the filaments from which are wound off by the motion of the bobbins, to which their ends are attached. About 12 inches above each basin is a piece of wire, covered with some soft substance; the filaments pass over these wires on their way from the basins to the bobbins, to cleanse and partially dry them. By this arrangement the winding into hanks, as performed by the silk growers abroad, the winding of bobbins from the hanks, and the usual cleansing process as performed by the throwster, are entirely dispensed with: a twisted thread of silk being furnished at one operation. Threads of different thicknesses may thus be produced, simply by increasing the number of cocoons in each basin. One girl can attend to the cocoons in 30 basins. Whenever a cocoon breaks or comes to an end, a new fastening is instantly made. By an adjustment of the bobbins and flyers, any amount of twist can be imparted to the thread, according to the purpose for which it is intended. The regularity of the movements leads to the production of a thread more free from knots than the ordinary reeled silk. There is no reeling, no hank; the silk is spun at once from the cocoons. The bobbins rotate 3000 times per minute. The principle of the cotton spindle and flyer being adopted, there is a power of adapting the apparatus to the production of many different kinds of thread; it can either be stopped at the *tram* stage, or advanced to that of *organzine*—terms that will be explained presently. There is said to be a more complete extraction of the silk from the cocoons, a greater regularity in the thread, a thorough extraction of lumps and knots, an avoidance of waste, and a saving in wages. These machines are gradually coming into use in Lancashire and on the continent; but there has not yet been organised an extensive importation of cocoons into England—without which, of course, the machines cannot work.

Silk Throwing and Weaving.—Except under the system just described, silk is imported in hanks, not in the cocoons. The silk in the hanks has simply been reeled, without regular twisting. In China and India the silk is reeled very unequally; there may be as few as five, or as many as fifteen filaments in each thread, without any regard to uniformity. Italian silk is better reeled. In the *throwing* mills, situated chiefly in Lancashire and Derbyshire, the silk is doubled, twisted, and hardened. John and Thomas Lambe introduced the art from Italy early in the last century. The silk is made into *dumb singles*, for weaving into gauze and other light fabrics; into *thrown singles*, which, when wound, cleaned, and thrown, is used for weaving into ribbons and common silks; into *tram*, which is doubled as well as thrown, and is used for the weft of the best kinds of goods; into *organzine*, used for the warp; and into *sewing silk*, which is the thickest and best of all. These kinds are produced by the processes of *winding*, *cleaning*, *doubling*, and *twisting*, carried to a greater or less extent. The *winding* is the transference of the silk to bobbins. The hanks are opened, and put upon light frames called *swifts*; and while these are rotating, a series of rotating bobbins draw off the silk from the swifts. *Fig.* 3 shows one form of apparatus for effecting this transfer. The *cleaning* is effected by passing the filament through a cleft in a piece of steel, whereby impurities and irregularities are removed. The *doubling* and *twisting* are processes in which two or more threads are twisted round each other; the machinery for effecting this is very varied; but a reference to Cotton Manufacture will afford means for judging of the general principle, although the details are different. *Fig.* 4 will illustrate the action of one form of twisting or throwing machine. When silk is required to be made very thick, strong, and densely twisted, it is sometimes twisted in the manner of rope, in a long alley or avenue (*fig.* 5). Silk *spinning* is comparatively a modern process. It is a mode of using up floss silk, and any waste that may result from the other processes. However unfitted silk may be to be thrown and twisted in the usual way, it may be spun into a continuous thread by carding, drawing, roving, and spinning, almost in the same manner as cotton. The thread produced is of inferior character, and is used for the cheaper kinds of goods.

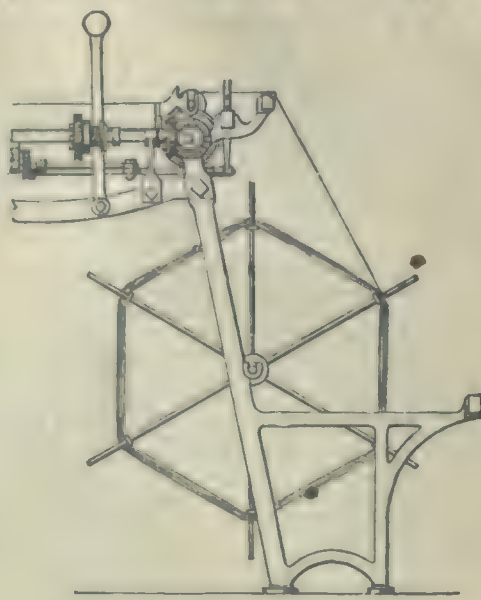

Fig. 3.—Silk Engine or Swift.

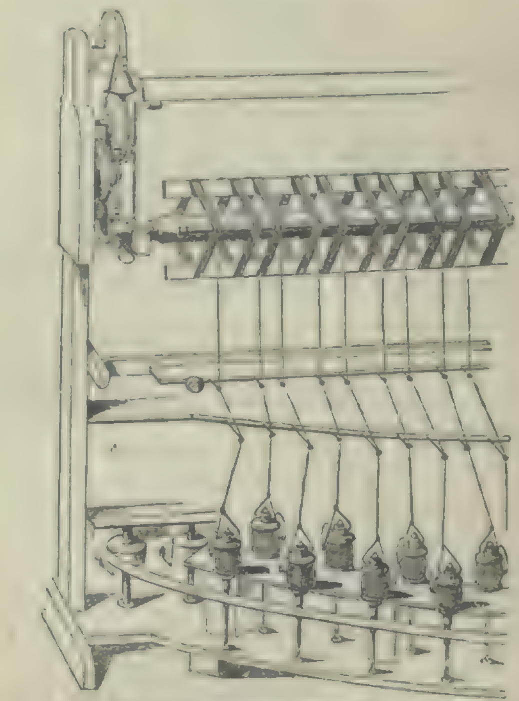

Fig. 4.—Twisting or Throwing Machine.

Of the subsequent processes in the silk manufacture, little need be said here. A reference to the articles Crape, Dyeing, Embroidery, Gauze, Jacquard Apparatus, Ribbon, and Weaving, will supply the requisite details. Brocade and damask, the most sumptuous articles of silk manufacture a century ago, are now comparatively unknown. Persian, sarsnet, gros-de-Naples, ducapes, satin, and levantines, are the names given to plain silks, which vary from one another only in texture, quality, or softness. Satin derives its lustre from the great proportion of the threads of the warp being left visible, and the piece being afterwards passed over heated cylinders. Other varieties of silk goods are produced by mechanical arrangements in the loom, such as using different shuttles with threads of various quality, &c. The pile which constitutes the peculiarity of velvet is produced by the insertion of short pieces of silk thread, which cover the surface so entirely as to conceal the interlacing of the warp and woof. The process of weaving velvet is slow, and it is paid for at several times the rate of plain silks. There are several sorts of goods in which silk is employed with woollen materials, such as poplins and bombazines. The Chinese make a species of washing silk, called at Canton ponge, which becomes more soft as it is longer used. Their crapes have never yet been perfectly imitated; and they particularly excel in the production of damasks and flowered satins.

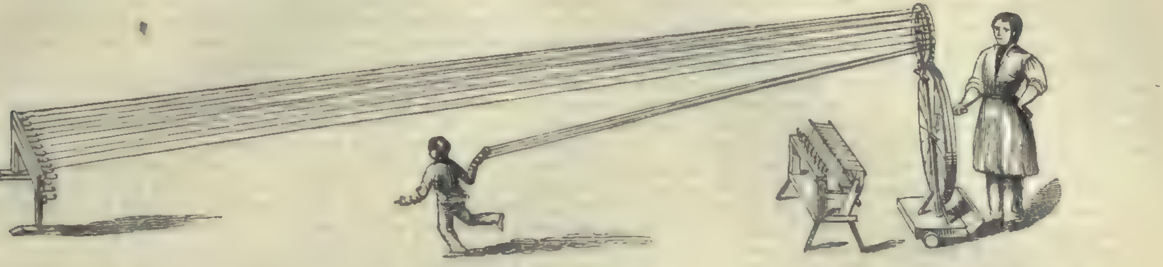

Fig 5.—Silk Spinning by hand.

Silk Trade.—The making of ribbons and small articles in silk long preceded in England that of broad silk. The trade was principally in the hands of women; and, like a sickly plant of foreign growth, it appears to have constantly demanded props and support. Repeated statutes and orders were made, discouraging the use of silk goods from abroad. An act passed in the reign of Edward IV. contained a sort of apology, which, if good for anything, made the prohibition unnecessary. The act states that not only were the artificers, men and women "greatly impoverished, hindered of their worldly increase and daily living, by these wares and chaffres being brought in fully wrought and ready for sale by strangers, the king's enemies, and other," but that "the greatest part in substance was deceitful, and nothing worth in regard of any man's occupation and profit." The law against the importation of ribbons, &c. was renewed at successive intervals until the 19 Henry VII., when it was made perpetual. Foreign ribbons notwithstanding still made their way over. The silk-throwsters were incorporated by a charter obtained 5 Charles I., about ten years after the establishment of the broad-silk manufacture in the reign of James I.: the silk-weavers were already included in the great company of weavers. Towards the end of the reign of Charles II., the silk manufacture, which had hitherto been almost confined to London, was carried into several other large towns of the kingdom by the French Protestants, who took refuge in this country, to the number, it is said, of 70,000, after the revocation of the Edict of Nantes in 1685; and amongst the rest to Coventry. The ribbon trade, of which Coventry has since become the chief seat in England, was introduced early in the last century by Mr. Bird, assisted probably by some of the French emigrants: the number of French terms still used in the manufacture proves that its origin was, in part at least, foreign. After the treaty of Utrecht, in 1713. French and Italian manufactured silks were admitted under considerable duties; but in 1765 the ribbon and other silk manufacturers procured the re-establishment of the prohibitory system, which was thenceforward maintained for sixty years, enforced by heavy penalties. With the increase of population and the greater demand for luxuries, the home market increased; but an export trade, principally to America, gradually decayed, in consequence perhaps of the heavy duties on raw and thrown silk. During the period of restriction, ribbon-weaving seems to have degenerated in this country as regards the superior branches. In 1824 the government determined to try the effect of an approach to free trade upon the silk manufacture. As a preliminary step, the duties on raw silk were reduced from 4*d.* per lb. to 3*d.*, and afterwards to 1*d.*; and on thrown, from 14*s.* 8*d.* to 7*s.* 6*d.*, and afterwards to 3*s.* 6*d.*, 2*s.*, and 1*s.* 6*d.*, according to quality; with a drawback to the amount of the duty allowed on any manufactures of silk exported, whether they were or were not made of the foreign thrown silk which had paid the duty. Two years were allowed after the lowering of these duties to prepare for the admission of foreign manufactured silk at a duty of 30 per cent. But this step was strongly opposed by the ribbon manufacturers of Coventry, who were unanimous in demanding a total prohibition of foreign ribbons; they succeeded in procuring, in 1832, the appointment of a committee of the House of Commons to inquire into the state of the silk trade. Nothing short of this (they said) could enable them to make ribbons at all. This inquiry led to no alteration in the system which the government had adopted; and subsequent remonstrances made by the same parties had a similar result.

Without tracing in detail the progress of the trade and the alterations in the duties, it will suffice to give a few figures relating to the last few years. Sir Robert Peel wholly removed the import duty on raw silk in 1845; and since that year every part of the trade has extended. The raw silk imported between 1844 and 1860, varied from 4,133,000 lbs. (in 1844) to 12,078,000 lbs. (in 1857). But the last-named year was an exceptional one, in regard to the largeness of the import; the import for the last seven years has averaged about 8,000,000 lbs. per annum. The above is *raw* silk, in the hank. The *thrown* silk, ready for the weaver, is imported in much smaller quantity, varying from 300,000 lbs. to 1,000,000 lbs. per annum. Manufactured silk goods imported are entered by the *lb.* or by the *piece*, according to their character—that is, European goods by the lb., and India goods by the piece. About 800,000 lbs. of broad silks and 400,000 lbs. of ribbons, from the continent, together with half a million pieces of India goods (Bandanas, Corahs, Choppas, Tussire cloths, Romals, and Taffetas)—have been about the average quantities within the last few years. Omitting all years but 1859, we will give the exact figures for that date:—

Raw silk, from China . . .	3,192,632	9,920,891 lbs.
" " India and Egypt .	5,805,487	
" " other countries .	922,772	
Waste, knubs, and husks		20,808 cwt.
Thrown silk, from France . .	155,872	327,462 lbs.
" " other countries .	171,590	
European blond, silk, and satin . .	305,523	987,080 lbs.
" gauze, crape, and velvet .	41,918	
" ribbons	479,106	
" plush for hats . . .	160,533	
India piece goods		843,084 pieces.

The *exports* of course do not comprise any *raw* silk. Of *thrown* silk, in the various forms of thread and yarn, the quantity exported from 1844 to 1860, varied from about 200,000 lbs. (in 1848) to 1,400,000 lbs. (in 1856). Of woven silk goods the quantity varied from 600,000 lbs. (in 1848) to 3,000,000 lbs. (in 1856). Taking one particular year (1858) as a fair average for seven recent years, we find that the computed real value of all the silk and silks imported was about 8,000,000*l.*; and that the declared value of the silk and silks exported was about 2,000,000*l.* Raw silk is imported duty free; manufactured goods pay an import duty, which in 1858 amounted to about 900,000*l.* By the new commercial treaty with France, England has given up about 300,000*l.* a year, that having been the produce of duties laid on French silk and silk goods.

Without going into details, it may suffice to state that the quantity of silk imported in 1860, whether raw, waste, or thrown, was less than in 1859; but greater in reference to manufactured silk. The export of silk goods woven in England was smaller in 1860 than in 1859; but of silk-thread and yarn, it was higher.

Mr. Winkworth, a Spitalfields manufacturer, estimated in 1857 that 50 millions sterling are sunk in the United Kingdom in the silk manufacture, and that 1,000,000 persons are supported by it. For the number of mills, see FACTORIES.

SILVER (Ag., from the Latin *argentum*). This metal has been known from the earliest times, frequent mention being made of it in the writings of Moses. Occurring naturally in the metallic state, though not so frequently as to render it common, and being easily worked, it must, no doubt, have been one of the first discovered metals. The alchemists and astrologers supposed it to have some mysterious connection with the moon, gave it the sign ☽, and called it *Diana* or *Luna*. They also seem to have been acquainted with chloride of silver (horn-silver) and nitrate of silver (lunar caustic).

Next to the free metal itself, the sulphide is the most important ore of silver. It is usually associated with sulphide of lead; indeed *galena* lead-ore nearly always contains silver, which is separated as described under LEAD, MANUFACTURE OF. The ore is roasted to expel sulphur, smelted with charcoal, and the argentiferous lead submitted to *cupellation* [ASSAYING], by which the lead, becoming oxidised, is partly volatilised, partly raked off the surface, and partly sinks into the cupel, leaving pure silver in the liquid state.

Another process for the extraction of silver from its ores is termed *amalgamation*, from the fact that the metal, after the ore has been roasted and the silver reduced by scrap iron, is dissolved out by mercury; the separated amalgam is afterwards submitted to distillation, when the mercury volatilises and the silver is left behind. [AMALGAM.] The processes, of which the final step is amalgamation, are many; the ores at different places, being associated with various matters, require different modifications of treatment. One metallurgist, Augustin, dispenses with the use of mercury altogether. Ziervogel at once obtains sulphate of silver by roasting the ore at a particular temperature, and precipitates the metal therefrom by copper.

Silver is almost pure white, having only the faintest tinge of red. In the native state it sometimes occurs crystallised in cubes or octohedra. It is moderately hard, elastic, and very ductile and malleable; one grain may be drawn into 400 feet of wire, and the thinnest silver-foil, or leaf-silver, has a thickness of only [illegible] of an inch. Silver melts at a bright red heat, and by repeated fusions becomes quite brittle. It volatilises in the luminous arc of a powerful electric current, yielding a beautiful green-coloured vapour. Of all metals, silver is, perhaps, the best conductor of heat and electricity. It does not oxidise at ordinary temperatures, but when melted has the property of absorbing many times its bulk of oxygen, which, however, is given out again at the moment of solidification. Though silver does not rust in the air, it rapidly tarnishes, owing to the formation of a thin film of sulphide of silver: this occurs more quickly in urban than in rural districts, sulphur in the form of sulphuretted hydrogen being far more abundant in the atmosphere of the former than in that of the latter localities.

Silver is not readily acted upon by alkalies, hence it is of peculiar value in the manufacture of vessels in which alkaline fusions have to be made. Common salt, especially in the melted state, is slowly decomposed by silver, soda being formed, from absorption of oxygen, while liberated chlorine attacks the metal. Boiling sulphuric acid oxidises silver; hydrochloric acid acts but slightly upon it; aqua regia attacks it readily; but its best solvent is nitric acid.

Perfectly pure silver may be obtained by dissolving the commercial metal in nitric acid, precipitating with hydrochloric acid, and then fusing the well-washed chloride with half its weight of dried carbonate of soda. In the place of carbonate of soda, carbonate of lime and charcoal are sometimes employed. Chloride of silver may also be reduced by placing it in contact with zinc and dilute sulphuric acid.

The equivalent of silver is 108.

Silver and *oxygen* form three compounds:—

1. Suboxide of silver	Ag_2O
2. Protoxide of silver	AgO
3. Peroxide of silver	AgO_2

1. *Suboxide of silver* (Ag_2O). Citrate of silver is heated to 212° in a current of hydrogen; on dissolving the resulting mass in water, and adding an alkali, the suboxide is precipitated as a black powder. When dry, it acquires metallic lustre under the burnisher.

Molybdate of suboxide of silver ($Ag_2O, 2MoO_3$). Wöhler forms this salt by passing hydrogen gas through an ammoniacal solution of molybdate of silver at 90°. It is a heavy brilliant black powder, in which occur regular octohedra. The *tungstate* of the suboxide is made in the same manner as, and much resembles, the molybdate. *Chromate* of suboxide of silver is black and amorphous.

2. *Protoxide of silver* (AgO). A brown *hydrated oxide* of silver is thrown down when solution of potash, soda, baryta, or lime is added to solution of nitrate of silver. It becomes anhydrous when heated to 140° Fahr., and is reduced to the metallic state by increased heat, by light, hydrogen, or almost any deoxidising agent. It is a powerful base, forming salts, the chief of which are presently described.

3. *Peroxide of silver* (AgO_2) occurs in dark gray acicular crystals when a solution of nitrate of silver is electrolysed. It accumulates on the positive pole, is a conductor of the electric current, but is very unstable.

Sulphide of silver. (AgS). The elements sulphur and silver have a great affinity for each other; the compound produced by their union occurs native in large quantities. [SILVER, in NAT. HIST. DIV.] Sulphide of silver may be formed artificially by passing a stream of sulphuretted hydrogen gas through a solution containing silver, or on adding a soluble sulphide to the silver solution, or, still more simply, by heating together sulphur and silver in their equivalent proportions.

Sulphide of silver readily fuses and cools to a dark-gray, crystalline mass, that is somewhat soft and malleable. It is decomposed and dissolved when heated with concentrated sulphuric or nitric acids, and is also readily attacked by strong hydrochloric acid. Potash, soda, iron, copper, or lead reduce it, by the aid of heat, to the metallic state.

Chlorine and silver form two compounds, namely:—

1. Subchloride of silver	Ag_2Cl
2. Protochloride of silver	$AgCl$

1. *Subchloride of Silver* (Ag_2Cl). When silver leaf is digested in solution of chloride of copper, or of perchloride of iron, black scales of subchloride of silver are produced. Nitric acid does not affect them, but ammonia resolves them into chloride of silver and metallic silver.

2. *Protochloride of Silver* ($AgCl$), *Chloride of Silver*, or, *Horn Silver*, is found native. [SILVER, in NAT. HIST. DIV.] It falls as a white, curd-like precipitate when hydrochloric acid or any soluble chloride is added to an aqueous solution of silver salt.

Chloride of silver is insoluble in water or dilute acids, and is only very slightly acted on by strong nitric or hydrochloric acids. It is somewhat more soluble in solutions of chlorides of alkalies or of alkaline earths, and is freely dissolved in solution of ammonia. It fuses when heated to about 500° Fahr., and on cooling forms a semi-transparent horn-like mass. It is partially reduced to the state of sub-chloride on exposure to light. A current of hydrogen removes the whole of the chlorine from heated chloride of silver; zinc, iron, and some other metals also reduce it to the metallic state. Chloride of silver forms double salts with alkaline cyanides, sulphites, and hyposulphites; the solutions of the last-named have a most intensely sweet taste, exceeding even that of sugar.

Bromide of Silver ($AgBr$) occurs native. It may be prepared artificially by precipitating nitrate of silver by bromide of potassium. It much resembles chloride of silver, but is less soluble in ammonia, and has moreover a yellow colour.

Iodide of Silver (AgI). This compound occurs native also. It falls as a yellow precipitate when an alkaline iodide is added to solution of nitrate of silver. It is insoluble in acids and nearly so in ammonia, but is very soluble in solution of iodide of potassium or hyposulphite of soda.

Sulphate of Silver ($AgOSO_3$). When silver is boiled in strong sulphuric acid, sulphate of silver is formed according to the following equation:—

$$\underbrace{Ag}_{\text{Silver.}} + \underbrace{2(HO, SO_3)}_{\text{Sulphuric acid.}} = \underbrace{AgO, SO_3}_{\text{Sulphate of silver.}} + \underbrace{SO_2}_{\text{Sulphurous acid.}} + \underbrace{2HO}_{\text{Water.}}$$

It is soluble in excess of the acid, but requires ninety parts of water to dissolve it.

Nitrate of Silver (AgO, NO_5). This salt, now so largely used in photography, and, when fused and cast into cylinders as an escharotic, under the name of *lunar caustic*, by surgeons, is formed on dissolving silver in strong nitric acid. By evaporation of the solution, colourless, transparent right rhombic crystals are deposited. It has an unpleasant bitter metallic taste, is soluble in water or alcohol, and is not decomposed by exposure to light unless in contact with organic matter. Solution of ammonio-nitrate of silver is formed by adding ammonia to nitrate of silver until the resulting precipitate is nearly all redissolved.

The following are the principal remaining salts of silver that are of interest. They are produced by the ordinary process of double decomposition.

The *triphosphate* ($3AgO, PO_5$) is of yellow colour, alterable by the action of light, readily soluble in excess of nitric acid or of ammonia.

The *pyrophosphate* ($2AgO, PO_5$) is white and easily fusible.

The *metaphosphate* (AgO, PO_5) occurs as a gelatinous mass, soluble in excess of nitrate of silver. The *carbonate* (AgO, CO_2) is at first white, afterwards pale yellow. The *borate* (AgO, BO_3) forms white flakes which turn violet on exposure to light. The *iodate* (AgO, IO_5) is white, and crystallises from ammonia in brilliant little rectangular prisms. The *chlorate* is soluble in water, and crystallises in white, opaque, four-sided prisms. The *monochromate* (AgO, CrO_3) is of a greenish-brown colour by reflected light and deep red by transmitted light. The *bichromate* ($AgO, 2CrO_3$) is a purple-red crystalline precipitate. The *arseniate* ($3AgO, AsO_5$) is a dark brick-red precipitate, soluble in ammonia and in carbonate of ammonia.

For the salts which silver forms with organic acids, see the articles on those acids.

Tests for Silver. The production of the white curdy chloride on the addition of hydrochloric acid, the precipitate being insoluble in hot nitric acid but readily soluble in ammonia, forms the characteristic test for silver salts. Reduction on charcoal in the blow-pipe flame, a black precipitate by sulphuretted hydrogen, and a yellow one on the addition of an alkaline iodide, are confirmatory tests.

Estimation of Silver. This is accomplished as described under ASSAYING, or in the state of well-washed and fused chloride, 100 parts of which contain 75·27 of metal.

SILVER, *Medical Properties of.* In a purely metallic state silver has no action on the animal frame, and the only salt much used is the nitrate, termed also *lunar caustic.* This is always fused in proper moulds, from which it is turned out in the form of cylinders, about three inches long, and the eighth of an inch in diameter. They are at first white, but quickly become of a dark gray or black colour, from combining with organic matter in the air. To prevent this the cylinders are generally wrapped up in blue paper. When nitrate of silver is brought in contact with any part of the human frame, it causes first a white mark, which gradually changes to blue, purple, and at last to black. This occurs more rapidly if moisture be present; and is owing to a chemical combination of the metal with the albumen and fibrin of the animal tissues. If the part be wetted, and the caustic applied several times at short intervals, vesication results. Nitrate of silver acts therefore locally as an *irritant* and *corrosive.* When taken internally in small doses for a considerable time, such as six or twelve months, it is absorbed and deposited in various parts of the body, and when it is deposited in the *rete mucosum* of the skin it causes discolorations, which in most cases prove permanent. It has been sometimes employed with success in the treatment of epilepsy, chorea, and some forms of *angina pectoris,* as well as morbid sensibility of the stomach. Larger doses can be borne when it is administered in the form of pill than in solution. The pills should be made with mucilage and sugar, but not with bread-crumb, as the common salt, or chloride of sodium, decomposes the nitrate and renders it inert. In cases of poisoning by nitrate of silver, common salt is a ready and effectual remedy: also milk. The liability of nitrate of silver to produce discolorations of the skin in persons taking it internally constitutes a serious objection to its employment, and there appears little necessity for giving it, since any case of epilepsy likely to be benefited by it will generally receive equal good from the use of *oxide of zinc*, without the risk of stains or other inconvenience.

The external employment of this agent is not liable to any objection when used cautiously, while its advantages are very great. It is the most powerful *direct antiphlogistic* agent known. All subacute inflammations in any part to which it can be immediately applied will subside under its influence. In inflammations not merely of the skin, but of mucous membranes when they occur in parts which are accessible, its influence is great and speedily manifested. Many of the cases of croup which in an advanced stage are unmanageable, begin in the back part of the throat (fauces), and if these parts are freely touched with a pencil dipped in a strong solution of nitrate of silver, the farther downward progress of the inflammation may be arrested. Similar benefit attends its use in *diphtheria*: for this a very strong solution in nitric ether is best. The same treatment is applicable to the erythematous inflammation which frequently begins either externally, and spreads through the mouth or nose to the fauces, and thence down the œsophagus, or originates in the fauces, leading to very serious results. Erysipelatous inflammation occurring in any part of the body may be effectually limited by nitrate of silver. For this purpose a complete circle should be formed round the inflamed part, but on the sound skin. For this case the solid cylinder, moistened at the end, is best. The circle must be perfect, or the morbid action may extend, escaping at the smallest breach. Chronic inflammation, and even ulceration, of the eyes, may be removed by nitrate of silver applied in different forms. Old indolent ulcers are stimulated to a healthy action by its use; and many cutaneous diseases removed by it. Recent burns have the severe pain often very much mitigated by it; but it must not in any of these cases be applied to too large a surface at once, as ill effects have followed such a practice. To specify all the uses of nitrate of silver would be impossible here, but one more deserves to be extensively known. It is the best application to chilblains, especially at first; but even after they break, it disposes them to heal.

When a solution of nitrate of silver is made, distilled water should invariably be used. The neglect of this rule causes many of the solutions applied to the eye to be not only useless, but hurtful. Oxide of silver has been strongly recommended as an antispasmodic, and not liable to the objections which attach to the nitrate. In preparing medicines with oxide of silver, care must be taken not to combine it with articles such as ammonia, lest an explosive compound should result.

SILVER WORKING. Silver-ores are found chiefly in veins which traverse the primary and the older of the secondary stratified rocks, but especially the former; and also the unstratified rocks, such as granite and porphyry, which are associated with the above. Some of the richest mines in South America are situated in primary strata; also in limestone and in grauwacke, and still more in secondary strata. In some of the mines of Peru, and in those of Kongsberg in Norway and Freiburg in Saxony, silver has been discovered in masses weighing from 100 to 800 lbs. In the mines of Europe the veins are numerous and slender; in some of the mines in the Harz Mountains and in the Hungarian mines the veins occur in a small number of spots, and are of considerable dimensions. In three of the richest districts of Mexico there is only one principal vein, which is worked in different places. One of these veins, in the district of Guanaxuato, is from 130 to 148 feet wide, and it has been traced and worked to an extent of nearly eight miles.

The average richness of all the ores in Mexico is from 3 to 4 ounces per quintal of 102 lbs. In one of the Mexican mines a working of 100 feet in length yielded in six months 432,274 lbs. troy of silver, equal in value to upwards of 1,000,000*l*. In Chili some of the mines yield only 8 oz. in 5000 lbs. of ore; but in the rich mine of Copiapo, discovered in 1832, the ore frequently contains 60 or 70 per cent. of silver. The average produce of the mines in Saxony is from 3 to 4 ounces in the quintal. The lead mines of Craven in Yorkshire contained 230 ounces of silver per ton; and those of Cardiganshire, worked in the reign of Charles I., yielded 80 ounces. The average proportion of the lead-mines of the north of England is 12 ounces per ton; but even when the proportion of silver is much less than this, it has been found profitable to separate it. The pure metal is separated from the ore by various processes; by mechanical division, roastings to separate the sulphur and other volatile matter, and melting at different stages of purification, with the addition of fluxes of various sorts. Refining is performed by amalgamation with quicksilver, the two metals being afterwards separated by distilling off the quicksilver. [Amalgam; Lead Manufacture, col. 149.]

When silver is issued for coin, it is always alloyed with copper; the maximum of hardness is produced by one-fifth of copper. One lb. of standard silver of the English coinage contains 11 oz. 2 dwts. of pure silver and 18 dwts. alloy, or 925 parts of pure silver in 1000 parts

of standard silver. [Money.] For purposes connected with the manufacture of various articles of use and ornament the alloy is greater. At Birmingham rolled sheets are made which do not contain more than 3 or 4 dwts. of silver to each lb. of the inferior metal. Silver forms by far the largest proportion of the value of domestic utensils in which either of the two precious metals is used. It has also been suggested that electro-plating with silver might be applied to the interior of leaden pipes, when used for domestic purposes.

The rolling of silver in contact with the inferior metals is performed by powerful flatting-mills. A bar of copper is made quite smooth and clean on one of its surfaces, it is then sprinkled over with glass of borax; a plate of fine silver is laid upon it, and the two are carefully bound together by wire. The mass is then exposed to a full red heat, which melts the borax and causes the silver to adhere to the copper. The ingot is now passed through a rolling-press and formed into a plate, both the silver and copper extending uniformly during the whole process, at the conclusion of which they are inseparably joined.

Mr. M'Culloch, on the authority of Mr. Birkmyre, gives an estimate of the quantity of silver produced in the two years next before, and the two years next after, the discovery of gold in California. According to this authority, in the year 1846 there was procured in America silver to the value of 5,261,619*l*., and in the other parts of the world 1,254,306*l*.; while in 1850 these values were raised to 7,259,824*l*. and 1,528,592*l*., respectively. It is interesting to note that, in 1857, more than 1,300,000 ounces of silver were obtained by refining lead in the lead-smelting works of the United Kingdom, of which about half a million ounces were from British lead.

It may suffice here to refer to several foregoing articles, for further information concerning the working of silver; such as Bullion; Gold Lace Manufacture; Mint; Money; Plate and Plating.

SILVER, GERMAN. [Copper; Tutenag.]

SILVERING, as a handicraft, is not always an example of silver-working, as the name would seem to imply; for in silvering looking-glass, no silver whatever is used, in the ordinary methods.

One mode of silvering, first adopted at Sheffield, is that of rubbing an amalgam of silver and mercury on the surface of any article of copper; by the application of heat the mercury is driven off; the silver, remaining behind, adheres firmly to the copper, and is susceptible of receiving a high polish. This is, chemically, analogous to the process of metal-gilding, or so-called "water-gilding," described under Gilding. The details, in the same article, concerning the application of leaf-gold, will nearly apply also to that of leaf-silver in the silvering of articles made of wood.

In an ordinary looking-glass, the reflection is derived from a film of mercury or quicksilver, in contact with the hinder surface of the glass, and fixed by amalgamating with a sheet of tin-foil. Silvering is here not a correct term, for there is no silver employed. The process is nevertheless a highly curious one. In the first place, a large sheet of tin-foil is unrolled, and laid down on a perfectly flat and very smooth stone table. Liquid mercury is poured on the foil, from the iron bottles in which it is imported, and made to float over the entire surface. The glass, made perfectly clean, is laid upon the mercury with a peculiar sliding movement, which suffices to remove the slight film of oxide which soon forms upon the surface, and also any air bubbles. The glass is then entirely covered with heavy leaden weights, which could not be done with safety unless the glass and the stone were perfectly flat. After remaining a day or two in this state, with the stone slightly inclined, it is found that all the superfluous mercury has been pressed out from between the glass and the foil; and, moreover, that the mercury has chemically combined with the foil, in such a way that both adhere firmly to the back of the glass.

In Mr. Drayton's process, nitrate of silver is combined with spirit and certain liquids, and is poured on the clean surface of the glass: a border of putty or some other substance being laid round the glass to retain the liquid. After remaining thus a few hours, the liquid is poured off, and a sediment of silver is found to be left adhering to the glass. This sediment or film is secured in its place by a varnish of bees' wax and tallow.

In Kidd's embroidered glass, the peculiarity of the process is that the patterns have the appearance of being in relief, or embossed on the exterior surface, and illuminated in frosted and burnished silver, whereas the whole of the processes are effected on the under surface.

Dr. Thomson's silvered vessels display great brilliancy and beauty. Glass vessels of any shape, and made of glass of any colour, are silvered within in such a way as to yield a reflection of great lustre. Some of the specimens, in which green and ruby glass are thus silvered, produce an effect which can hardly be paralleled in any other manufacture. The surface is often richly cut and diversified, and the silvering may be made to appear at any spots selected by the workman. The silvering agent is one of the salts or compounds of silver, as in Drayton's process; but arrangements of an intricate kind are requisite to the due production of the required effects.

Dr. Faraday has described at the Royal Institution a mode of silvering introduced by M. Petitjean. A solution of oxide of silver, ammonia, nitric acid, and muriatic acid is employed. A cast-iron table-box is provided, with water within and gas underneath. The sheet of glass to be silvered is laid upon the iron plate and heated to 140° Fahr. by gas flames acting through or on the water. The solution is poured on the glass, together with a little polishing-powder. When well floated, the solution is rolled with an india-rubber roller to expel all air-bubbles. Then more solution is poured on, and more heat applied, until a precipitate of pure silver is deposited on the glass, which takes place in about a quarter of an hour. The surplus liquid being poured off, and the silver washed, it is found to present a beautiful reflecting surface. No mercury being here employed, the process is less harmful than that usually adopted.

SIMARUBA BARK is obtained from the root of the *Simaruba amara*, Aublet. *S. officinalis*, Dec. It is a native of Guyana, and also of Jamaica (unless this latter be a distinct species), and the more southern of the United States.

It is intensely bitter, and yields an infusion more bitter than the decoction. The infusion made with cold water is best. It may be used as an emetic or tonic, in fever and dysentery; also, against worms. If the wood be used in cooking, the viands acquire an intense bitterness. The *Simarouba versicolor* (Aug. St. Hilaire), a native of Brazil, has similar properties, but its internal use causes stupor and other narcotic symptoms. This effect might be avoided by making the infusion with *cold water*, as in the case of quassia. [QUASSIA.]

SIMILAR, SIMILAR FIGURES (Geometry). Similarity, resemblance, or likeness, means sameness in some, if not in all, particulars. In geometry, the word refers to a sameness of one particular kind. The two most important notions which the view of a figure will give are those of *size* and *shape*, ideas which have no connection whatsoever with each other. Figures of different sizes may have the same shape, and figures of different shapes may have the same size. In the latter case they are called by Euclid *equal*, in the former *similar* (similar figures, *δμοια σχήματα*). The first term [EQUAL; RELATION], in Euclid's first use of it, includes united sameness both of size and shape; but he soon drops the former notion, and, reserving equal to signify sameness of size only, introduces the word similar to denote sameness of form: so that the equality of the fundamental definition is the subsequent combined equality and similarity of the sixth book.

Similarity of form, or, as we shall now technically say, similarity, is a conception which is better defined by things than by words; being in fact one of our fundamental ideas of figure. A drawing, a map, a model, severally appeal to a known idea of similarity, derived from, it may be, or at least nourished by, the constant occurrence in nature and art of objects which have a general, though not a perfectly mathematical, similarity. The rudest nations understand a picture or a map almost instantly. It is not necessary to do more in the way of definition, and we must proceed to point out the mathematical tests of similarity. We may observe indeed that errors or monstrosities of size are always more bearable than those of form, so much more do our conceptions of objects depend upon form than upon size. A painter may be obliged to diminish the size of the minor parts of his picture a little, to give room for the more important objects: but no one ever thought of making a change of form, however slight, in one object, for the sake of its effect on any other. The giant of Rabelais, with whole nations carrying on the business of life inside his mouth, is not so monstrous as it would have been to take the ground on which a nation might dwell, England, France, or Spain, invest it with the intellect and habits of a human being, and make it move, talk, and reason: the more tasteful fiction of Swift is not only bearable and conceivable, but has actually made many a simple person think it was meant to be taken as a true history.

Granting then a perfect notion of similarity, we now ask in what way it is to be ascertained whether two figures are similar or not. To simplify the question, let them be plane figures, say two maps of England of different sizes, but made on the same projection. It is obvious, in the first place, that the lines of one figure must not only be related to one another in length in the same manner as in the other, but also in position. Let us drop for the present all the curved lines of the coast, &c., and consider only the dots which represent the towns. Join every such pair of dots by straight lines: then it is plain that similarity of form requires that any two lines in the first should not only be in the same proportion, as to length, with the two corresponding lines in the second, but that the first pair should incline at the same angle to each other as the second. Thus, if L Y be the line which joins London and York, and F C that which joins Falmouth and Chester, it is requisite that L Y should be to F C in the same proportion in the one map that it is in the other; and if F C produced meet L Y produced in O, the angle C O Y in one map must be the same as in the other. Hence, if there should be 100 towns, which are therefore joined two and two by 4950 straight lines, giving about 12 millions and a quarter of pairs of lines, it is clear that we must have the means of verifying 12¼ millions of proportions, and as many angular agreements. But if it be only assumed that similarity is a possible thing, it is easily shown that this large number is reducible to twice 98. Let it be granted that *l y* on the smaller map is to represent L Y on the larger. Lay down *f* and *c* in their proper places on the smaller map, each with reference to *l* and *y*, by comparison with the larger map: then *f* and *c* are in their proper places with reference to each other. For if not, one of them at least must be altered, which would disturb the correctness of it with respect to *l* and *y*. Either then there is no such thing as perfect similarity, or else it may be entirely obtained by comparison with *l* and *y* only.

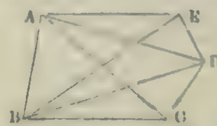
We have hitherto supposed that both circumstances must be looked to; proper lengths and proper angles; truth of linear proportion and truth of relative direction. But it is one of the first things which the student of geometry learns (in reference to this subject), that the attainment of correctness in either secures that of the other. If the smaller map be made true in *all* its relative lengths, it must be true in all its directions; if it be made true in *all* its directions, it must be true in all its relative lengths. The foundation of this simplifying theorem rests on three propositions of the sixth book of Euclid, as follows:—

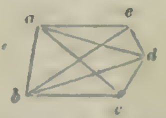
1. The angles of a triangle (any two, of course) alone are enough to determine its form: or, as Euclid would express it, two triangles which have two angles of the one equal to two angles of the other, each to each, have the third angles equal, and all the sides of one in the same proportion to the corresponding sides of the other.

2. The proportions of the sides of a triangle (those of two of them to the third) are alone enough to determine its form, or if two triangles have the ratios of two sides to the third in one the same as the corresponding ratios in the other, the angles of the one are severally the same as those of the other.

3. One angle and the proportion of the containing sides are sufficient to determine the form of a triangle: or, if two triangles have one angle of the first equal to one of the second, and the sides about those angles proportional, the remaining angles are equal, each to each, and the sides about equal angles are proportional.

From these propositions it is easy to show the truth of all that has been asserted about the conditions of similarity, and the result is, that any number of points are placed similarly with any other number of points, when, any two being taken in the first, and the corresponding two in the second, say A, B, and *a*, *b*, any third point C of the first gives a triangle A B C, which is related to the corresponding triangle *a b c* of the second, in the manner described in either of the three preceding propositions. For instance, let there be five points in each figure:

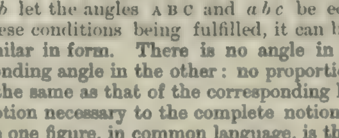


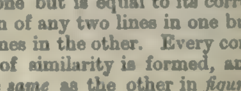


In the triangles B A E and *b a e*, let the angles A E B and E B A be severally equal to *a e b* and *e b a*. In the triangles A D B and *a d b* let D A : A B : : *d a* : *a b*, and D B : B A : : *d b* : *b a*. In the triangles A C B and *a c b* let the angles A B C and *a b c* be equal, and A B : B C : : *a b* : *b c*. These conditions being fulfilled, it can be shown that the figures are similar in form. There is no angle in one but is equal to its corresponding angle in the other: no proportion of any two lines in one but is the same as that of the corresponding lines in the other. Every conception necessary to the complete notion of similarity is formed, and the one figure, in common language, is the *same* as the other in *figure*, but perhaps on a different scale.

The number of ways in which the conditions of similarity can be expressed might be varied almost without limit; if there be n points, they are twice ($n-2$) in number. It would be most natural to take either a sufficient number of ratios, or else of angles: perhaps the latter would be best. Euclid confines himself to neither, in which he is guided by the following consideration:—He uses only salient or convex figures, and his lengths, or sides, are only those lines which form the external contour. The internal lines or diagonals he rarely considers, except in the four-sided figure. He lays it down as the definition of similarity, that all the angles of the one figure (meaning only angles made by the sides of the contour) are equal to those of the other, each to each, and that the sides about those angles are proportional. This gives $2n$ conditions in an n-sided figure, and consequently four redundancies, two of which are easily detected. In the above pentagons, for instance, if the angles at A, E, D, C, be severally equal to these at *a*, *e*, *d*, *c*, there is no occasion to say that that at B must be equal to that at *b*, for it is a necessary consequence: also, if B A : A E : : *b a* : *a e*, and so on up to D C : C B : : *d c* : *c b*, there is no occasion to lay it down as a condition that C B : B A : : *c b* : *b a*, for it is again a consequence. These points being noted, the definition of Euclid is admirably adapted for his object, which is, in this as in every other case, to proceed straight to the establishment of his propositions, without casting one thought upon the connection of his preliminaries with natural geometry.

Let us now suppose two similar curvilinear figures, and to simplify the question, take two arcs A B and *a b*. Having already detected the test of similarity of position with reference to any number of points, it





will be easy to settle the conditions under which the arc A B is altogether similar to *a b*. By hypothesis, A and B are the points corresponding to *a* and *b*. Join A, B, and *a*, *b*; and in the arc A B take any point P. Make the angle bap equal to BAP, and abp equal to ABP; and let ap and bp meet in p. Then, if the curves be similar, p must be on the arc ab; for every point on AB is to have a corresponding point on ab. Hence the definition of similarity is as follows:—Two curves are similar when for every polygon which can be inscribed in the first, a similar polygon can be inscribed in the second.

It is easily shown that if on two lines, A and a, be described a first pair of polygons, P and p, and a second pair, Q and q, the proportion of the first and second pairs is the same, or $P : p :: Q : q$. The simplest similar polygons are squares; consequently, any similar polygons described on A and a are to one another in the proportion of the squares on A and a. This is also true if for the polygons we substitute similar curves; and it must be proved by the method of exhaustions [GEOMETRY], or by the theory of limits applied to the proposition, that any curve may be approached in magnitude by a polygon within any degree of nearness.

The theory of similar solids resembles that of similar polygons, but it is necessary to commence with three points instead of two. Let A, B, C, and a, b, c, be two sets of three points each, and let the triangles ABC and abc be similar: let them also be placed so that the sides of one are parallel to those of the other. If then any number of similar pyramids be described on ABC and abc, the vertices of these pyramids will be the corners of similar solids. If P and p be the vertices of one pair, then the pyramids $PABC$ and $pabc$ are similar if the vertices P and p be on the same side of ABC and abc [SYMMETRY], and one of the triangles, say PAB, be similar to its corresponding triangle pab, and so placed that the angle of the planes PAB and CAB is the same as that of the planes pab and cab. The simplest similar solids are cubes; and any similar solids described on two straight lines are in the same proportion as the cubes on those lines. Similar curve surfaces are those which are such that every solid which can be inscribed in one has another similar to it, capable of being inscribed in the other.

It is worthy of notice that the great contested element of geometry [PARALLELS] would lose that character if it were agreed that the notion of form being independent of size is as necessary as that of two straight lines being incapable of enclosing a space; so that whatever form can exist of any one size, a similar form must exist of every other. There can be no question that this universal idea of similarity involves as much as this, and no more; that in the passage from one size to another, all lines alter their lengths in the same proportion, and all angles remain the same. It is the subsequent mathematical treatment of these conditions which first points out that either of them follows from the other. If the whole of this notion be admissible, so in any thing less; that is, the admission implies it to be granted that whatever figure may be described upon any one line, another figure having the same angles may be described upon any other line. If then we take a triangle ABC, and any other line ab, there can be drawn upon ab a triangle having angles equal to those of ABC. This can only be done by drawing two lines from a and b, making angles with ab equal to BAC and ABC. These two lines must then meet in some point c, and the angle acb will be equal to ACB. If then two triangles have two angles of one equal to two angles of the other, each to each, the third angle of the one must be equal to the third angle of the other; and this much being established, it is well known that the ordinary theory of parallels follows. The preceding assumption is not without resemblance to that required in the methods of Legendre. [PARALLELS.]

SIMILE is defined by Johnson to be "a comparison by which anything is illustrated or aggrandised," a definition which has been often neglected by poets. A metaphor differs from a simile in expression, inasmuch as a metaphor is a comparison without the words indicating the resemblance, and a simile is a comparison where the objects compared are kept as distinct in expression as in thought. The metaphor is only a bolder and more elliptical simile. When we speak of the rudeness of a man, and say, "Mr. Jones is as rude as a bear," we use a simile, for the rudeness of the two are kept distinct but likened; when we say "that *bear* Mr. Jones," we use a metaphor, the points of resemblance being confounded in the identification of rudeness with a bear. So, "brave as a lion" is a simile—the "lion Achilles" a metaphor. Where the resemblance is obvious, it may be more forcibly and as intelligibly expressed by a simple metaphor; but when the resemblance is not so obvious, it requires fuller elucidation, and then it must be expressed by a simile. Similes therefore, from their tendency to detail, are usually misplaced in passionate poetry, but metaphors constitute the very language of passion; for the mind, when moved, catches at every slight association to express itself, but never dwells on them with the deliberateness of a comparison.

SIMILOR. A kind of gold-coloured brass. [BRASS.]

SIMONY. [BENEFICE.]

SIMOOM. [SAMIELL.]

SIMPLE BODIES. [ATOMIC THEORY.]

SIMPLE CONTRACT debts are those which are contracted without any engagement under the seal of the debtor or of his ancestor [DEED], and which are not of record by any judgment of a court. Money due for goods bought by the debtor is the most usual of simple contract debts; and the declaration against a defendant, in an action for goods sold, usually alleges that the defendant undertook (or contracted) to pay the plaintiff the sum due. Simple contract debts are the last which are payable out of a deceased person's estate, when the assets are insufficient.

SIN. One of the few passages of Scripture in which we have something which approaches to the character of a definition relates to this word: "Sin is the transgression of the law." (1 John iii. 4.) Within this definition would be comprehended all actual sins, when the word law is interpreted to mean the Christian law, the rule by which the minds of all who profess Christianity are bound; not merely open palpable offences against the law, such as murder, theft, lying, and the like, but sinful omissions of duty, and those sins which are only those of contemplation and thought: since the Christian rule commands us not to neglect the performance of our duties, and to keep a watch over the thoughts as well as over the actions and words.

It was this comprehensive and most excellent law which was in the mind of the Apostle when he said that "sin was transgression of the law," or at least that other divine law which bound the conscience of the Jews. But the expression may be taken to express more generally any law which a person holds in his conscience to be binding upon him, whether it be a law of nature only, or a law in which the natural perception of right and wrong is modified by and mixed with what is received as the will of God concerning us by direct revelation from him.

When the word sin is applied to any act, it is always, among correct writers or speakers, used with reference to religious obligation, and to the responsibility in which we stand to God, and the liability in which we are to future punishment. "To do wrong" would express the same act as "to commit sin;" but we use the former phrase without thinking of the offence which is done against God in any act of the kind; not so when we use the other phrase.

Under this definition it is evident that there may be degrees in sin: and we mention this to remove what we deem an erroneous opinion on this subject, which goes the length of saying that there is really no difference between the slightest violation of any moral obligation and the more heinous transgressions. The error on this point arises out of one of the commonest mistakes in respect of language—confounding words in their abstract with words in their concrete state. It is true that sin in the abstract is one and indivisible, and there are no degrees in it; it expresses that which is most offensive in the sight of a pure, holy, and judging God. But when we say "a sin," we refer to some particular act; and common sense tells us that in all acts in which the law is trangressed there is not the same amount of moral turpitude, not the same amount of defiance to the Divine Power, nor the same injury to society or to our neighbour, and consequently not the same amount of offence in the sight of God. But a watchful guard should be kept; for nothing is more certain in the philosophy of mind, than that small offences lead imperceptibly to the toleration of greater, so that the man who thinks little of small offences may become, before he is aware, guilty of those of the most heinous nature.

There is also what divines call Original Sin; a phrase which is differently interpreted by different persons. By some it is considered as being the act of sin committed by our first parents when they transgressed the law which had bound them not to eat of the fruit of a certain tree; and this act of sin is regarded as partaken in by all the posterity of Adam, fixing upon them all the guilt of his sin, and exposing them to punishment which would be inflicted for this particular sin, to say nothing of their own sin, but for the great redemption. There are many modifications of this notion and many shades of opinion; and some classes of professing Christians do not use the phrase original sin, though they admit the proneness of man to sin; attributing it to his ignorance and imperfection, to the violence of his appetites and passions, and in general referring it to that state of probation in which it seems to them to have been the intention of the Creator to place us.

SINAMINE. [THEISINAMINE.]

SINAPIC ACID ($2HO, C_{22}H_{10}O_8$).—A product of the action of caustic potash on SINAPINE. The *sinapate of potash* ($2KO, C_{22}H_{10}O_8$) thus produced is decomposed by hydrochloric acid, and the precipitated sinapic acid crystallised from hot diluted alcohol. Sinapic acid forms small prisms which are insoluble in ether and only slightly soluble in water. Both itself and its salts are somewhat unstable. It fuses above 300° Fahr.

SINAPINE. ($C_{32}H_{23}NO_{10}$). The hydrosulpho-cyanate of sinapine occurs in white mustard. After the mustard flour has been successively treated with ether and with absolute alcohol to remove fatty and colouring matter, it is boiled in alcohol of sp. gr. 0·825, and the filtered liquid concentrated till, on cooling, it deposits crystals. Sinapine reduces the salts of copper, silver and gold. Its solutions are very liable to decompose into SINAPIC ACID and SINKALINE; a change that is rapidly effected by ebullition with solution of potash:—

$$\underbrace{C_{32}H_{23}NO_{10}}_{\text{Sinapine.}} + 2(KO,HO) = \underbrace{2KO, C_{22}H_{10}O_8}_{\text{Sinapate of potash.}} + \underbrace{C_{10}H_{13}NO_2}_{\text{Sinkaline.}} + 2HO$$

Sinapine was formerly called *sulphosinapisine*.

SINA'PIS. Two species of this genus are used in this country to yield the mustard of commerce, *S. alba* and *S. nigra*, or white mustard and black mustard. Both are annuals, the latter extensively cultivated in Yorkshire and Durham. Of the former the seeds are large, smooth, not veined or reticulated, and when bruised and mixed with water, do not evolve a pungent odour. The integument or skin is also thin, and the quantity of fixed oil obtained from it is less than from that of the black mustard. White mustard is of a light colour externally (but one variety is blackish), and when reduced to powder, is of a light yellow colour.

The seeds of black mustard are about the size of the head of a common pin, ovate-globose, of a reddish-brown, beautifully veined, internally yellow, oily, and yielding a yellowish-green powder. The chemical constitution of the two is essentially different, as it is only the black mustard which evolves, when bruised and mixed with water, the pungent principle which irritates the eyes, nostrils, and skin. The white mustard possesses a non-volatile acrid principle, which is developed by the addition of water; also a peculiar principle, sulpho-sinapisin. It is the young plants from this species which are eaten with cress as a salad.

The fixed oil is perfectly bland, like that of olive or rape, which last it greatly resembles. It exists to the extent of 20 per cent in white, and about 28 per cent. in black mustard-seed. To obtain it the seeds are crushed in a mill or between rollers, and the skins should be subjected to pressure as well as the farina or flour. The cake may then be sifted and reduced to a fine powder, as it retains all the pungent properties. In France the oil is generally left in the seeds, which renders them very difficult to powder, and makes it expensive. It is also less potent than English mustard in equivalent quantity. The marc or cake is sometimes used as manure, but this is a waste. It has been supposed to be anthelmintic as well as purgative, but its medicinal properties are insignificant.

Pure flour of mustard ought alone to be used for medical purposes, but it is seldom to be met with; the mustard of the shops is a mixture of the flour of both black and white mustard with wheat flour and capsicum.

Flour of mustard, mixed with water, forms the well-known condiment so much used with all the more indigestible articles of food, the solution of which it seems to favour by rousing the powers of the stomach. A tea or table-spoonful of mustard in a tumbler of water forms a ready and useful emetic in many cases of poisoning, especially when narcotic poisons have been taken; also in cholera. Added to foot-baths, mustard has a revulsive action, which is often serviceable in the commencement of colds, and when gout has seized the stomach or brain; also when cutaneous diseases have suddenly receded. (RUBEFACIENTS.)

Sinapisms are generally directed to be made with vinegar, but water of the temperature of about 100° Fahr. is preferable, and less expensive. French mustard for the table is often prepared with vinegar.

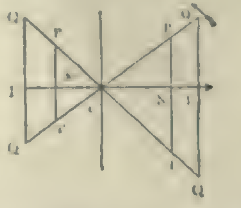
S. nigra differs from the white mustard in the flowers being much smaller, and in the seeds being black. The great purpose for which the black mustard is grown is for the seeds. "To raise the seed for flour of mustard and other officinal occasions, sow either in March or April in an open compartment, or large sowings in fields, where designed for public supply. Sow moderately thick, either in drills six or twelve inches asunder, or broad-cast, after the ground has been properly ploughed and harrowed, and rake or harrow in the seed. When the plants are two or three inches high, hoe or thin them moderately where too thick, and clear them from weeds. They will soon run up to stalks, and in July, August, or September return a crop of seed ripe for gathering; being tied up in sheaves and left three or four days on the stubble." (Don's Miller.) Rain damages the crop very much. Black mustard exhausts the soil rapidly. When once grown it is difficult to extirpate on account of the great vitality of the seeds, which, if buried at almost any depth and for any length of time, will germinate when brought to the surface. In preparing the flour of mustard in this country, the black husk of the seed is separated by delicate sifting. This process, which is not gone through on the Continent, makes the British mustard so much lighter and more agreeable in colour.

SINAPOLINE. [MUSTARD, OIL OF.]

SINDOC, or SINTOC (a word not to be confounded with Sindhooka, or Sinduya, the Indian name of the *Vitex Negundo*), is the bark of a species of cinnamomum (*C. sintoc*, Blume), a native of the forests of Java. It greatly resembles the bark of *Cinnamomum culilawan*, Blume, and partakes of the qualities of Ceylon cinnamon in a very inferior degree. The bark is in thick flat pieces, not in thin quill-like pipes. Its oil is like that of cassia. The bark is used as a spice; the oil as a medicine and perfume by the natives. It is seldom brought to Europe in any shape.

SINE and COSINE. We separate from the article TRIGONOMETRY the mere description and properties of these fundamental terms, which, though originally derived from simple trigonometry, are now among the most useful foundations of mathematical expression. For what we have to say on their history, we refer to the article just cited.

According to the ancient system of trigonometry, the sine and cosine are only names given to the abscissa and ordinate of a point, not with reference to the position of that point in space, but to the radius vector of that point and its angle. Thus, measuring angles from the line ON, and in the direction of the arrow, the angle NOP has an infinite number of sines and cosines. With reference to the *radius* OP, PN is the sine and ON the cosine of ∠ NOP; but with reference to the radius OQ, QR is the sine and OR the cosine. The fundamental relation



$$(\text{sine } \theta)^2 + (\text{cosine } \theta)^2 = (\text{radius})^2$$

is obvious enough.

The student always began trigonometry with this multiplicity of definitions, and with the idea of some particular radius being necessary to the complete definition of the sine and cosine. But as he proceeded, he was always taught to suppose the radius a unit; that is, always to adopt that line as a radius which was agreed upon to be represented by 1. Hence he gradually learned to forget his first definition; and, passing from geometry to arithmetic, to use the following: PO being unity, the sine of NOP is PN, which is therefore in arithmetic the fraction which PN is of PO; and the cosine is the fraction which ON is of PO. If QO had been used as a unit, the result would have been the same; for by similar triangles, RQ is the same fraction of QO which NP is of PO.

In the most modern trigonometry, and for cogent reasons, the student is never for a moment allowed to imagine that the sine and cosine are in any manner representatives of lines. In a practical point of view, the final definition of the old trigonometry coincides exactly with that of the new; but the latter has this advantage, that all subsequent geometrical formulæ are seen to be homogeneous in a much more distinct manner. The definition is this: The sine of NOP is not NP, nor any number to represent NP; it is the fraction which NP is of PO, considered as an abstract number. Thus if ON, NP, PO, be in the proportion of 3, 4, and 5, PN is $\frac{4}{5}$ of OP: this $\frac{4}{5}$ is the sine of NOP, not $\frac{4}{5}$ of any line, nor any line considered as $\frac{4}{5}$ of a unit; but simply $\frac{4}{5}$, four-fifths of an abstract unit. Similarly the cosine is the fraction which ON is of OP. In just the same manner the abstract number π, or 3·14159 . . ., is not styled (as it used to be) the circumference of a circle whose diameter is a unit, but the proportion of the circumference to the diameter, the number of times which *any* circumference contains its diameter. We cannot too strongly recommend the universal adoption of this change of style, a slight matter with reference to mere calculation of results, but one of considerable importance to a correct understanding of the meaning of formulæ.

The line OP being considered as positive [SIGN], the signs of PN and NO determine those of the sine and cosine; and the manner in which the values of these functions are determined when the angle is nothing, or one, two, or three right angles, is easy enough. The following short table embraces all the results of sign :—

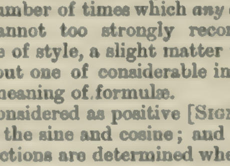
	0		I		II		III		IV
Sine	0	+	1	+	0	−	1	−	0
Cosine	1	+	0	−	1	−	0	+	1.

Read this as follows :—When the angle $=0$, the sine $=0$; from thence to a right angle the sine is positive: at the right angle the sine is $+1$; from thence to two right angles the sine is positive, &c.

The fundamental theorems of the sine and cosine, from which all their properties may be derived, are,

$$\sin(a+b) = \sin a \cos b + \cos a \sin b$$
$$\sin(a-b) = \sin a \cos b - \cos a \sin b$$
$$\cos(a+b) = \cos a \cos b - \sin a \sin b$$
$$\cos(a-b) = \cos a \cos b + \sin a \sin b$$

all which theorems are in fact contained in any one of them, so soon as that one is shown to be universally true. It frequently happens however that the student is allowed to assume the universal truth of these theorems upon too slight a foundation of previous proof: drawing a figure for instance in which both angles are less than a right



angle. We give, as an instance, the proof of the first formula when both angles are greater than two right angles. Let X O P $=a$, P O Q $=b$, both angles being measured in the direction of revolution indicated by the arrow. The sum is four right angles + X O Q, which has the same sine and cosine as X O Q. From any point Q in O Q draw perpendiculars on O X and O P, and complete the figure as shown. Then sin $(a+b)$ is positive, and is the fraction which Q M is of Q O, or Q M : Q O; Q M and Q O being expressed in numbers. But

$$\frac{QM}{QO} = \frac{QS}{QO} + \frac{NR}{QO} = \frac{QS}{QN}\frac{QN}{QO} + \frac{NR}{NO}\frac{NO}{QO}$$

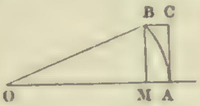
$$\text{By similar triangles} = \frac{OT}{PO}\frac{QN}{QO} + \frac{PT}{PO}\frac{NO}{QO}.$$

Now, remembering the magnitudes of a and b, and the rule of signs established, we have

$$\sin a = -\frac{PT}{PO},\ \cos a = -\frac{OT}{PO},\ \sin b = -\frac{QN}{QO},\ \cos b = -\frac{NO}{QO};$$

and substitution immediately gives the first formula. We shall not here dwell on the minor consequences of these formulæ, but shall refer to the collection in TRIGONOMETRY.

The connection of the sine and angle depends in great part upon the following theorem:—if x may be made as small as we please, $\sin x : x$ may be made as near to unity as we please. Observe that this theorem supposes the angle x to be measured by the theoretical unit [ANGLE], or the angle 1 to be the angle of which the arc and radius are equal. The proof depends upon the assumption that in the adjoining obvious figure the arc A B is less than its containing contour A C + C B.



If the radius O B be r, we see that x must be arc A B : r, or A B $=rx$. Also B M $=r \sin x$, B C $=$ A M $=r-r\cos x$, by definition. Now the arc A B is greater than B M, and less than B M + M A, or rx lies between $r \sin x$ and $r\sin x+r-r\cos x$, or x lies between $\sin x$ and $\sin x+1-\cos x$;

$$\text{or between } \sin x \text{ and } \sin x + \frac{\sin^2 x}{1+\cos x};$$

$$\text{whence } \frac{x}{\sin x} \text{ lies between 1 and } 1 + \frac{\sin x}{1+\cos x}.$$

Hence, x diminishing without limit, the difference between 1 and $x : \sin x$ diminishes without limit, and therefore that between 1 and $\sin x : x$ which was to be proved. From hence it follows that $1-\cos x$ and $\frac{1}{2}x^2$ approach to a ratio of equality, as may be readily proved from the equation

$$1-\cos x = \frac{x^2}{2}\cdot\left(\frac{\sin x}{x}\right)^2\cdot\frac{2}{1+\cos x}$$

in which the second and third factors have unity for their limit. Hence then, when x is very small, x and $1-\frac{1}{2}x^2$ are very near representatives of the sine and cosine; and the goodness of the representation may be increased to any extent by diminishing x.

The complete theory of the sine and cosine, from and after the two theorems just established, depends upon the introduction of the square root of the negative quantity. If we take ordinary algebra only, in which the impossible quantity is unexplained, we have the most common mode of proceeding. The explanations afterwards given would make this theory the most simple imaginable, to a student who had learned ALGEBRA from the beginning in the manner pointed out. To take the middle course, let us assume the rules of algebra [OPERATION] independently of the meanings of the symbols. Let $\sin x$ and $\cos x$ be defined as "such functions of x that $\sin(x+y)$ gives $\sin x.\cos y+\cos x.\sin y$, and $\cos(x+y)=\cos x.\cos y-\sin x.\sin y$." Observe that we do not in thus defining say there *are* such functions; we only say, *if there be* such, let them have these names. Then, as in ALGEBRA cited above, we see that if $\phi x=\cos x+\sqrt{-1}.\sin x$, the relation $\phi(x+y)=\phi x\times\phi y$ follows; whence [BINOMIAL THEOREM] ϕx can be nothing but K^x, where K is independent of x. Let $x=1$, whence $\phi(1)=K$, or we have

$$\cos x+\sqrt{-1}.\sin x=(\cos 1+\sqrt{-1}.\sin 1)^x \ldots (1)$$

and similarly it is shown that

$$\cos x-\sqrt{-1}.\sin x=(\cos 1-\sqrt{-1}.\sin 1)^x \ldots (2).$$

From these we get, by multiplication,

$$\cos^2 x+\sin^2 x=(\cos^2 1+\sin^2 1)^x: \ (3)$$

if it be possible, let $\cos^2 1+\sin^2 1=1$, then $\cos^2 x+\sin^2 x$ is always $=1$, or at least [ROOT] we may always take one pair of forms satisfying this condition. Hence, making $\cos 1+\sqrt{-1}.\sin 1=e$, we have $\cos 1-\sqrt{-1}.\sin 1=e^{-1}$, and the two equations give

$$\cos x = \frac{e^x+e^{-x}}{2} \quad \sin x = \frac{e^x-e^{-x}}{2\sqrt{-1}} \quad (4)$$

which will be found to satisfy all the conditions used in defining them, namely,

$$\frac{e^{x+}+e^{-x-y}}{2} = \frac{e^x+e^{-x}}{2}\ \frac{e^y+e^{-y}}{2} - \frac{e^x-e^{-x}}{2\sqrt{-1}}\ \frac{e^y-e^{-y}}{2\sqrt{-1}}$$

$$\frac{e^{x+y}-e^{-x-y}}{2\sqrt{-1}} = \frac{e^x-e^{-x}}{2\sqrt{-1}}\ \frac{e^y+e^{-y}}{2} + \frac{e^x+e^{-x}}{2}\ \frac{e^y-e^{-y}}{2\sqrt{-1}}$$

$$\left(\frac{e^x+e^{-x}}{2}\right)^2 + \left(\frac{e^x-e^{-x}}{2\sqrt{-1}}\right)^2 = 1$$

To determine what algebraical formula e must be, take the universal formula

$$e^x = 1+\log e.x+(\log e)^2\frac{x^2}{2}+(\log e)^3\frac{x^3}{2.3}+\ldots$$

whence we easily get from (4)

$$\sin x = \frac{\log e}{\sqrt{-1}}.x+\frac{(\log e)^3}{\sqrt{-1}}\frac{x^3}{2.3}+\frac{(\log e)^5}{\sqrt{-1}}\frac{x^5}{2.3.4.5}+\ldots\ldots$$

$$\cos x = 1+(\log e)^2\frac{x^2}{2}+(\log e)^4\frac{x^4}{2.3.4}+\ldots\ldots$$

Now e, as far as our definitions have yet extended, is wholly undetermined, every value of e being applicable. Let us add to our conditions that $\sin x : x$ shall approach to unity as x is diminished without limit: but $\sin x : x$ approaches to $\log e : \sqrt{-1}$; therefore $\log e=\sqrt{-1}$, or $e=\epsilon^{\sqrt{-1}}$.

The preceding is purely symbolical; we merely ask how are previous symbols, used under certain laws, to be put together so as to represent certain new symbols which are to have certain properties. Let us now take the real geometrical meaning of $\sin x$ and $\cos x$, and the complete system of algebra, in which $\sqrt{-1}$ is explained. In that system, if a line equal to the unit-line be inclined to it at an angle x, it is obviously represented by $\cos x+\sqrt{-1}.\sin x$, and any power of it, whole or fractional, can be obtained by changing x into mx, so that

$$\cos mx+\sqrt{-1}.\sin mx=(\cos x+\sqrt{-1}.\sin x)^m$$

is an immediate consequence of definition; and making $x=1$, the equation

$$\cos m+\sqrt{-1}.\sin m=(\cos 1+\sqrt{-1}.\sin 1)^m$$

follows at once. To prove that $\epsilon^{\sqrt{-1}}$ and $\cos 1+\sqrt{-1}\sin 1$ are identical, in the most logical manner, requires a previous definition of an exponential quantity, in a sense so general, that exponents of the form $a+b\sqrt{-1}$ shall be included: without this the new algebra just referred to is not free from the results of INTERPRETATION.

However we may proceed, the series above given for the sine and cosine of x become

$$\sin x=x-\frac{x^3}{2.3}+\frac{x^5}{2.3.4.5}-\frac{x^7}{2.3.4.5.6.7}+\ldots$$

$$\cos x=1-\frac{x^2}{2}+\frac{x^4}{2.3.4}-\frac{x^6}{2.3.4.5.6}+\ldots$$

and these series are always convergent. Their present form depends entirely on the unit chosen; if however by x we mean x°, x', or x'', we must write

$$\sin x=ax-\frac{a^3x^3}{2.3}+\frac{a^5x^5}{2.3.4.5}-\ldots$$

$$\cos x=1-\frac{a^2x^2}{2}+\frac{a^4x^4}{2.3.4}-\ldots$$

where [ANGLE] a is ·01745,32925 ...., ·00029,08882, ..., ·00000,48481, ... according as x means a number of degrees, of minutes, or of seconds.

The preceding is enough on the fundamental meanings of these terms, and on their connection with algebra. Some applications will be seen in TRIGONOMETRY.

SINE and COSINE, CURVES OF. By the curve of sines is meant that which has the equation $y=\sin x$, and by the curve of cosines, that which has the equation $y=\cos x$; it being understood that x stands for as many angular units as there are linear units in the abscissa. The undulatory forms of these curves are easily established; and if the ordinate of a curve consist of several of them, as in $y=a\sin x+b\cos x+c\sin 2x$, the several parts of the compound ordinate may be put together in the same manner as that in which the simple undulations are compounded in ACOUSTICS. Except as expressing the most simple form of undulating curves, these equations are of no particular use in geometry.

SINE-CURE. Sine-cures are ecclesiastical benefices without cure of souls, and are of three sorts:—1. Where the benefice is a donative

[Benefice], and is committed to the incumbent by the patron expressly without cure of souls, the cure either not existing or being entrusted to a vicar; this is the strictest sine-cure. 2. Certain cathedral offices, namely, the canonries and prebends, and, according to some authorities, the deanery. 3. Where a parish is destitute, by some accident, of parishioners; this last kind has been called depopulations, rather than sine-cures.

Rectors of a parish in which vicars were likewise established with cure of souls have often by degrees exempted themselves from their ecclesiastical functions, and so have obtained sine-cures; but this is rather by abuse than legitimately. Sine-cures are exempt from the statute of pluralities.

SINETHYLAMINE. [Theisinamine.]

SINKALINE. ($C_{10}H_{13}NO_2$)—This alkaloid is a derivative of Sinapine. It is best obtained by heating hydro-sulphocyanate of sinapine with baryta water until precipitation of sinapate of baryta ceases; then taking out hydrosulphocyanic acid by the sulphate of copper and iron; again adding excess of baryta water, and lastly separating baryta by a current of carbonic acid. From the solution of carbonate of sinkaline, thus obtained, the other salts may be formed by double decomposition. The alkaloid itself is produced by the action of oxide of silver on hydrochlorate of sinkaline.

Solution of sinkaline is very unstable. Evaporated in vacuo, a crystalline mass of the alkaloid is obtained, soon becoming brown in contact with air. *Chloroplatinate of sinkaline* contains ($C_{10}H_{13}NO_2$, HCl, $PtCl_2$).

SINKING FUND. [National Debt, col. 878.]

SIOUX INDIANS. [North American Indians.]

SIPHON (*σίφων*), a tube or pipe by which a liquid can be decanted from one vessel to another without inverting or disturbing the vessel from which the liquid is withdrawn. This machine was probably invented in the second century B.C., by Hero of Alexandria, who, in the 'Spiritalia,' or 'Pneumatics,' mentions its employment for the purpose of conveying water from one valley to another over the intervening ground.

The siphon is a bent tube the arms of which are of unequal length: one of the arms being immersed in the liquid which is to be drawn from a vessel or reservoir, and the air being removed by suction, or by means of a syringe, or by previously filling the siphon, the liquid in the vessel immediately rises in the immersed arm, in consequence of the pressure of the atmosphere on that which surrounds the tube; then passing over the bend, it flows from the open orifice at the lower extremity of the other arm. When the fluid to be raised is water, the vertical height of the bend in the tube, above the surface of the water in the vessel, must not exceed about 33 feet, because a column of water of that height would be in equilibrium with the pressure of the atmosphere, and could not by the latter be forced over the bend. If mercury were to be raised, the height of the bend in the siphon must, for a similar reason, be less than 30 inches. The external arm of the siphon must be longer than that which is immersed in the fluid, or its orifice must be on a lower level than the surface of that fluid, in order that the weight of the column of fluid in the former may exceed that in the latter, and thus a continual stream be produced.

The siphon is sometimes furnished with a suction or exhausting pipe at the side, by means of which the air can be conveniently removed and the liquid be made to rise over the bend into the longer limb. In the *Wurtemberg siphon* the two ends are turned up, so that when once filled it will always remain so, and act at once when one end is immersed into a liquid.

A siphon may be made to discharge water at the upper extremity by means of an air-vessel at that place. Thus, while the tube is filled with water, if the communication between the descending branch and the lower part of the air-vessel be closed by the shutting of a valve, the water, which would have otherwise descended, rises in the vessel, where it condenses the air; and, from the reaction of the latter, it is made to escape, as in a forcing-pump, through an open pipe whose lower extremity is under the surface of the water in the vessel. This was the invention of M. Hachette, and is denominated the *ram siphon*.

In order that a fluid may issue from that branch of a siphon which is on the exterior surface of the vessel containing it, it is necessary, as has been stated above, that the extremity of the branch should be below the level of the surface of the fluid in the vessel; but it may be observed that there is an exception to the rule when the interior diameter of that branch is very small; for example, when it is less than 1-10th of an inch, the interior diameter of the branch in the vessel being considerably greater. For if such a fluid as water or wine be introduced into a bent tube having one branch only very small, and the open ends be uppermost, the top of the fluid in the more slender branch will, by the effect of capillary attraction, stand higher than the top of that in the other branch. It would follow therefore, that if the bent tube were inverted, and the orifice of its larger branch were placed under the surface of the fluid in a vessel, the fluid would begin to issue from the other branch, though the orifice of the latter were a little above the level of that surface.

The effect of a siphon may be produced by capillary attraction alone; for if a piece of cotton cloth have one of its extremities in a vessel of water, and part of it be made to hang over the edge of the vessel, the water will be attracted along the threads of the cloth, and will descend from thence in drops, provided the extremity of the part thus hanging over be below the surface of the water in the vessel.

The phenomena presented by springs of water are explained by supposing that the rain which is absorbed in the earth occasionally finds its way by small channels to some interior cavity, and from thence by other channels, which may be considered as natural siphons, to an orifice on a lower level at the surface of the ground. At this orifice it issues in a stream of water, which continues to flow till the surface of the water in the cavity has descended below the tops of the vertical bends in the channels: the water then ceases to flow till the rains again raise the water in the cavity above those bends. But it sometimes happens that a spring, without ceasing to flow, discharges periodically greater and smaller quantities of water in given times; and this is accounted for by supposing the existence of two cavities either unconnected or communicating with one another by small channels. The channels leading from one of these cavities to the point of efflux are supposed to be below the level of the water in both cavities, so that the water flows through them continually; but if the channels from the other have vertical bends, so that they act as siphons, and at the same time these channels carry off the water in them faster than it can flow from the first cavity to the second, it will be only when the water in the latter cavity is above the level of all such bends that a discharge will take place from thence. As the water in that cavity may only attain the necessary height in consequence of periodical falls of rain, it will follow that corresponding increases in the total quantity of water discharged can only then take place.

For the amusement of young persons, several philosophical toys have been constructed, in which the effects are produced by means of concealed siphons. The siphon is sometimes placed within a figure in the middle or on the edge of a cup, and sometimes between its exterior and interior sides. Such are *Tantalus's Cup* and the *Siphon Fountain*.

SIPHON GAUGE, in pneumatics, is a tube of glass bent so as to form two branches equal and parallel to one another, and each from 6 to 8 inches in length; the tube is hermetically closed at one end and left open at the other. One of the branches is filled with mercury; and, both of them being in vertical positions, with the closed and open ends upwards, they are, by means of a brass stem terminating in a screw, affixed generally to the under surface of the table carrying the plate of an air-pump. The siphon is contained in a cylindrical glass vessel, a little exceeding it in length, which is closed at the lower and open at the upper extremity; and the open end of the cylinder is screwed to the table of the air-pump immediately about the orifice of a brass tube which passes through the pump-plate and opens into the receiver placed upon the plate, so that there is a free communication between the air in the cylinder, in the open leg of the siphon, and in the receiver. This gauge has a scale of inches, decimally subdivided. While the pressure of the air in the receiver and in the open branch of the gauge is more than a counterbalance to the weight of the column of mercury in the closed branch, the gauge presents no indications: from the time however that, by continuing the process of exhausting the receiver, the pressure of the air in the open branch becomes less than the weight of the column of mercury in the other, that column descends in the latter branch and rises in the former; and then the degree of rarefaction in the receiver is indicated by the difference between the heights of the columns of mercury in the two branches of the siphon. [Air-Pump; Pear-Gauge.]

SIRENS (*Σειρῆνες*) are described in the 'Odyssey' as two maidens who sat by the sea and so charmed with their music all who sailed by, that they remained on the spot till they died. Ulysses, by the direction of Circe, had himself tied to the mast, and stopped the ears of his companions with wax, by which means he was able to hear their music, and escape from its influence. ('Od.' xii. 39, &c., 169.) The ship of Ulysses, with himself tied to the mast, is frequently represented on gems, and other works of ancient art. The number of the Sirens was afterwards increased to three, who are variously named by different writers, Parthenope, Ligeia, and Leucosia; or Aglaope, Peisinoë, and Thelxiepia. They were usually called the daughters of Melpomene and Achelous (Apollod., i. 3, § 4), and were represented by artists with the feathers and wings of birds. (Compare Ovid, 'Met.,' v. 522, &c.) According to the later writers they were urged by Hera to contend with the Muses, who conquered them, and tore off their wings. (Paus., ix. 34, § 2.)

SIRIUS and PROCYON (*Σείριος* and *Προκύων*), the Greek names of the bright stars in the constellations of the Great and Little Dog [Canis Major and Minor]. These are Orion's dogs, according to some, and those of minor personages, according to others; the whole of their mythic explanations form a strong proof, in addition to those already noticed, that the constellations are not Greek in their origin. The Egyptians called the dog-star Sothis [Sothiac Period], and from its heliacal rising had warning that the overflow of the Nile was about to commence. Now the overflow of the Nile follows the summer solstice; whereas, by the precession of the equinoxes, the heliacal rising of Sirius is now about the tenth of August. This heliacal rising is a very indefinite phenomenon, and will serve any system: by it Bailly, from Bainbridge's calculations, was able to carry back the settlement of Egypt 2800 years before Christ: while Newton, by a reckoning made on the same principles, made many ancient events seem later than was generally supposed.

The greatest heats of summer generally follow the summer solstice, and in the Mediterranean latitudes, and in ancient times, it was observed that the unhealthy and oppressive period coincided with the heliacal rising of the dog-star. We say *the* dog-star, without specifying whether it was Sirius or Procyon; it is uncertain which it was, and may have been both, for the heliacal risings do not differ by many days. All antiquity attributed an evil influence to the star; and though Geminus among the ancients, and Petavius among the moderns, thought that the effects were to be attributed to the sun alone, they had hardly any followers until the fall of judicial astrology. Even at this day, when the heats of the latter part of the summer are excessive, we are gravely told that we are in the dog-days; and most of the almanacs, in which an absurdity has the lives of a cat, persist to this very year in informing us that the dog-days begin on the 3rd of July, and end on the 11th of August. Now as the heliacal rising of Sirius takes place about the very end of this period, it is clear that the cart has got before the horse, or the mischief before the dog. Moreover, it is notorious that in our island the oppressive heats of the summer, during which dogs are apt to run mad (which is what many people think the name arises from, as indeed it was anciently recorded among the effects of the star), generally fall about the middle or end of August. The real classical dog-days are the twenty days preceding and the twenty days following the heliacal rising of whichever star it was, Sirius or Procyon. It is perfectly useless to retain this period: surely these dogs have had their day.

SIROCCO is the name given to a hot and suffocating wind which appears to originate with the rarefied air in the sandy deserts of Arabia, about the season that the overflowing of the Nile commences; it extends eastward over Arabia, Persia, and some parts of Hindustan, and it is felt, but with less inconvenience, in Italy and Spain. This wind is probably only one of the modifications of that which, in different countries, is called *samoom*, *simoom*, *samm* or *samieli*, *khamsin*, and *harmattan*. [SAMIELI.]

SISSOO (*Dalbergia Sissoo*), a tree well known throughout the Bengal presidency, and highly valued on account of its timber. It is common chiefly in the forests and beds of rivers which extend all along the foot of the Himalayas up to 30° N. lat. The trunk is generally more or less crooked, lofty, and often from three to four feet in diameter. The Sissoo yields the Bengal shipbuilders their crooked timbers and knees. Dr. Roxburgh describes it as being tolerably light, remarkably strong, but not so durable as could be wished; the colour is light grayish-brown, with dark veins: he says that upon the whole he scarcely knows any other tree more deserving of attention, from its rapid growth in almost every soil, its beauty, and uses. Captain Baker, in his 'Experiments on the Elasticity and Strength of Indian Timbers,' describes the Sissoo in structure somewhat resembling the finer species of teak, but as being tougher and more elastic, and as employed by the natives for house furniture, beams, cheeks, spokes, naves and felloes of wheels, keels and frames of boats, blocks, and printing-presses. It is universally employed both by Europeans and natives of the north-west provinces where strength is required. *S. Dalbergia Ougeinensis*, found in central India, is also highly valued for timber: the pillars of Sindia's palace at Ougein are made of it.

SISTRUM, a musical instrument of percussion, of great antiquity, constructed of brass, and shaped like the frame and handle of a racket, the head part of which had three, and sometimes four, horizontal bars placed loosely on it, which were tuned, most probably, by some scale, and allowed to play freely, so that when the instrument was shaken, piercing, ringing sounds must have been produced. Some writers have confounded the sistrum with the cymbals, though the instruments could have had nothing in common except their harsh metallic sounds.

SIVA, the personification of the destroying principle, forms, with the two other gods, Brahma and Vishnu, the Trimûrti, or triad, of the Hindus; and although, in allusion to his office as destroyer, he is classed third, yet he is generally allowed to occupy the second place among the Hindu deities, or even (according to some) the first, as his supremacy appears to have obtained more general assent than that of Vishnu. Indeed the worship of Siva is so predominant, that Brahma, who is the only one of the three mentioned by Manu, and who seems to have enjoyed a larger share of adoration in ancient times, has now only one temple in India, while Mahâdeva (a name of Siva) and the adventurous Vishnu, whose incarnations attract so much of the veneration of the Hindus, are, in fact, the only gods of the whole Hindu pantheon who have numerous worshippers. The present popular form of Siva worship in all probability assumed its actual state before the great Saiva reformer, Sankara Acharya, who lived in the eighth or ninth century. ('Vishnu Purâna,' pref., p. x.) This opinion is supported by the well-founded assertion that the Saiva faith was instituted by Paramata Kalânala, who is described in the 'Sankara Vijaya' of Ananda Giri as teaching at Benares, and assuming the insignia that characterise the Dandis, a sect of Saivas of modern times. ('As. Res.,' xvi. 22.) No allusion is made in the Purânas to the original power of this god as destroyer; that power not being called into exercise till after the expiration of twelve millions of years, when, according to Puranic accounts, the Kaliyuga will come to a close together with the universe; and Mahâdeva is rather the representative of regeneration than of destruction. The linga is the only form under which Siva is now adored in most parts of India. According to Professor Wilson ('Vishnu Purâna,' xliv.), "There is nothing like the phallic orgies of antiquity; it is all mystical and spiritual." The linga is twofold, external and internal. The ignorant, who need a visible sign, worship Siva through "a mark" or "type," which is the proper meaning of the word "linga," of wood or stone; but the wise look upon this outward emblem as nothing, and contemplate in their minds the invisible inscrutable type, which is Siva himself. But his other forms are many, and they vary in so far as they attribute to him the qualities of creator, preserver, destroyer, and regenerator, and represent him in his various *avatâras* (incarnations), eight of which are called by the common name of Bhairava, all alluding to terrific properties of mind or body. He is sometimes seen with two hands, at others with four, eight, or ten, and with five faces; he has a third eye in his forehead, the corners of which are perpendicular, which is peculiar to him; a crescent in his hair, or on his forehead, encircling the third eye; he wears ear-rings of snakes, and a collar of skulls. Mahâdeva, when represented thus, but with one head, has four hands, in one of which he holds a pâsa, the use of which is to extract the souls out of the bodies of men, when their time is come, and is a common attribute of Yama, the god of death ('S. Sâvitryupakhyana,' ed. Bopp.), a tris'ula is upheld by the other, and the two other hands are in a position of benediction. As Bhairava (the lord of dread) he is frightful to behold; great tusks burst through his thick lips; the hair, which is stiff and erect, gives his face a dreadful aspect; the fall of the necklace is impeded by numerous snakes which twine round his body. This is also the idol which shows him as Mahâ-kâla, or god of time. It is in this character that he is supposed to delight in bloody sacrifices, and that the Saiva Sannyâsis (followers of Siva who practice the yoga to the highest degree) inflict on themselves the cruelties which have rendered so conspicuous the temple of Jaggernaut (Jagannâtha, the lord of the world). [YOGA.] A very minute account of the fortitude and self-denial of the deluded Yogis is given in Ward's 'View of the Religion of the Hindus.' His consort Sakti, who in her corresponding character is celebrated as the goddess Durgâ or Kâlî, participates in these horrible sacrifices, and has of late years become more notorious by the exposure of the homicidal practices of the Thugs, who recognise in her their tutelary divinity. Siva is also the god of justice. In that character he rides a white bull, the symbol of divine justice (Manu, viii. 16), and is often seen with the *parashu* (battle-axe) in his hand, and the sacred string. On pictures he is often represented as if rubbed over with ashes, and with a blue neck; the epithet of Nîlakanta (blue-necked) was given to him in commemoration of his having drunk the poison which arose from the sea, and threatened to destroy mankind. But the character in which he is more generally known, and which his followers imitate, is that of the Kapâla-bhrit (skull-bearer). Skanda-Purâna makes him describe himself in the following words:—"Pârvatî (his bride) must be foolish to practise so severe a penance in order to obtain me, Rudra (one of his 1000 names), a wandering mendicant, a bearer of a human skull, a delighter in cemeteries, one ornamented with bones and serpents, covered with ashes and with no garments but an elephant's skin, riding on a bull, and accompanied by ghosts and goblins." Now this, except that the unearthly beings who follow him are represented by a crowd of dirty people, is exactly the description of a Saiva digambara (sky-clad, that is, naked—a kind of religious mendicants), if, instead of the god's third eye, we add a round dot on the nose, made of clay or cow-dung, and a mark on the forehead, composed of three curved lines, instead of the *chandra* (half moon) which Rudra obtained at the churning of the ocean.

To continue the account of his adventures: Siva marries Pârvatî, and lives with her in the midst of the eternal snows of Mount Kailâsa. His heaven is however one of the most splendid in Hindu mythology, and a description of it may be found in Ward's 'View;' it is a translation from the Kritya Tatwa. There also are his two sons; Ganesa, the leader of the heavenly choristers, and, as Vigneswara, the god of difficulties, whose head is that of an elephant; and Kartikeya, the six-faced god of war. It is there that he was thus addressed by Brahma and the other gods:—"I know that thou, O Lord, art the eternal Brahm, that seed which, being received in the womb of thy Sakti (aptitude to conceive), produced this universe; that thou, united with thy Sakti, dost in sport create the universe from thy own substance, like the web from the spider." Here it was that he reduced to ashes the "flowery-bowed mind-bewitcher" Kâma (the god of love), pierced by whose arrows he had neglected to avenge the wrong done to him and his consort by his father-in-law Daksha. On the top of Kailâsa it is that the worshippers of Siva will be admitted to the sports of the inhabitants, where Mahâdeva invented for the amusement of his bride the heavenly dance, to which his faithful attendant Nandi plays the musical accompaniment. There lie before the door his vehicle, the white bull, and the tiger on which his consort rides. Though wanting all the splendours of the Swarga (Indra's heaven), the abode of Siva, when drawn in the glowing colours of the East, is no less gratifying. From thence he is supposed to bless his worshippers, "when, with Pârvatî on his knees, he, the lord of the world, on whose brow shines the moon throwing its beams over the mountain of the north, deigns to allow the Suras and Asuras (gods and dæmons) to wear for their frontal ornament the reflection of the radiance of the nails of his feet, and the Ganga, rushing from the top of his head, refreshes the air of his sacred dwelling" (*Kathá Sarit Ságara*). This is a favourite subject among the Hindu painters, and we must allow that their conception of it is generally well executed.

The numerous names of Siva have led Europeans into a notion contrary to that which induced the Hindus to make the linga the general type for all the forms of this god; they naturally enough supposed each of his numerous names and pagodas to belong to a distinct and separate deity. Hence the erroneous notion about polytheism in India, whilst it is evident that the original monotheism of Hindu religion had in the progress of time become pantheism, which is prevalent all over the East. Even at present the follower of Siva denies the divinity of Vishnu, and *vice versâ*; although both these gods, now representing the Supreme Being, were only types of divine qualities attributed to the Trimûrti. But the allegory eventually acted too strongly on the imagination of the people. Brahma, as creator, had finished his work, and could not with propriety act any more. Siva therefore and Vishnu were destined to do all that fancy could suggest; but still Mahâdeva is the only god to the Saivas, whilst Narâyana is the one chosen by the Vaishnavas. For this we have the express words of the Radha Tantra, which says that the form of Arddhanareswara (half man, half woman) was assumed by Siva in order to prove that he was the one Brahm, in whom both the female and male powers are united. This notion of the animating and recipient principles being united in one, has been embodied in the statue termed Arddhanarî; one half of Siva, from head to foot, bears all the ornaments of Pârvatî or Bhâvanî; the other is exactly the same as that in which he is usually exhibited.

The rage for identifying the gods of the Eastern nations with those of the West has not spared Siva. He was Bacchus, and Saturn, and Pluto; in fact, he was said to be almost the entire pantheon of Greece and Rome and Egypt. Neither is this to be wondered at, seeing that the Greeks and Latins ascribed different attributes to different deities. The Hindus have only one to whom to ascribe all attributes. Siva is also, and it appears originally, the representative of fire. This element penetrates earth and water, represented by Brahma and Vishnu, imparts to them some of its vigour, develops their qualities, and brings everything in nature to that state of increase, maturity, and perfection which they would not attain without it. But ceasing to act beneficially on the created things, they perish: this agent of reproduction, when free and visible, consumes the body, the composition of which he himself had effected: to this quality he owes his title of god of destruction.

The reader who may wish to see the connection of the Hindu gods with those of Greece and Rome will find ample materials in the papers which Col. Wilford inserted in the earlier volumes of the 'Asiatic Researches:' they cannot however be implicitly relied on.

SIVAN (in Hebrew, סִיוָן) is the ninth month of the Jewish civil year. The name is mentioned in the Bible, at Esther viii. 9. In the copies of the calendar of Heliopolis (Balbek) we find Εζηρ, Οζιρ, and Οζιζ; but these words are evidently intended to represent the Syrian month Heziran. No probable Hebrew etymology has been suggested for the word Sivan; but Renfey proposes the Persian month Sefendarmed, which the analogous Zend form shows to be compounded of two words, the first of which, 'spenta,' signifies *pure*. Sivan has thirty days, and it coincides with our May or June; in the year 1860 it began on the 22nd of May and ended on the 20th of June; in 1861 it begins on the 10th of May and ends on the 8th of June. On the 6th of this month Pentecost begins, and some festivals are mentioned as held on the 15th, 16th, and 17th of the month, in commemoration of victories gained by the Maccabees; but they do not appear to be generally observed. The same may be said of certain fasts set down for the 25th and 27th, in remembrance of the death of celebrated rabbis.

SIX CLERKS. The office of Six Clerks was an office of great antiquity connected with the Court of Chancery, probably as ancient as the court itself. The number of the Six Clerks was limited to six as long ago as the 12th Rich. II. The history of this office illustrates the mischief of attempting to regulate the supply of legal services to the client. It exhibits an instance of the principles of interference and monopoly destroying two successive classes of officers, in spite of the strongest support which the law and the courts could give to them.

The Six Clerks were originally the only attorneys of the court. By the common law, any person who was impleaded in any of the courts of law was bound to appear in person, unless he obtained the king's warrant, or a writ from Chancery enabling him to appear by attorney, "by reason whereof," says Lord Coke (1 'Inst.,' 128), "there were but few suits." There are many early statutes still in force enacted for the purpose of empowering the subject to appoint an attorney. The earliest statute is that of Merton (A.D. 1235), whereby it is "provided and granted that every freeman which oweth suit to the county, tithing, hundred, and wapentake, or to the court of his lord, may freely make his attorney to do those suits for him." Subsequent Acts extended this privilege to other parties and other courts; but to this day it would appear that, by the strict law of the land, except so far as it has fallen into desuetude, persons in good health, in pleas relating to money, are bound to appear in person. None of these statutes, however, extended to courts of equity; but, as far as appears, every person who was desirous of relief, or compelled to defend himself in the Court of Chancery, was obliged to employ one of the Six Clerks as his representative.

In early times great exertions were made to limit the number of attorneys who were allowed to practise in each court. The increase of litigation which accompanied the increase of property was looked on as an evil to be checked in every possible method; and the method most relied on was that of limiting the number of legal practitioners. The well-known statute of 1455 (33 Hen. VI., c. 7, which is still in force) may be referred to as an instance. It recites a practice of contentious attorneys to stir up suits for their private profits, and enacts that there shall be but six common attorneys in Norfolk, six in Suffolk, and two in Norwich, to be elected and admitted by the chief-justice. As late as the year 1616 a rule was made, "that the number of attorneys of each court be viewed, to have them drawn to a competent number in each court, and the superfluous number to be removed." These various regulations, so far as they were enforced, could only have been detrimental to the public; and as regards the courts of King's Bench and Common Pleas, they seem not to have been long insisted on. As to the Exchequer, the principle of monopoly was continued in force down to the year 1830, until which time eighteen attorneys only were admitted to practise in it. As a consequence, that court was, before the year 1830, scarcely at all resorted to. Since that time more actions are commenced in it than in any other court. In the year 1632 a new principle was introduced into the common-law courts, and all persons wishing to be attorneys were required to serve an attorney under articles for six years (since reduced to five). The Six Clerks' Office, however, did not adopt this method until long after. They got over the difficulty by admitting under-clerks, afterwards called sworn clerks, to practise in their names, and they shared in some way or other the profits with them. In 1548 an inquisition was appointed, to inquire into the supposed exactions and abuses of the Court of Chancery, and the fees then payable for the business of this office. The presentment shows that all the fees payable for business done in this office were at that time payable to the Six Clerks; and it contains no allusion whatever to the under-clerks as being in any way known as officers of the court. They seem at that time to have held a position with regard to the Six Clerks quite analogous to that which the solicitors for a long period were under with regard to the sworn clerks, and to have been the real persons who prosecuted the causes. They must have been numerous, as in 1596 an order was made limiting the number that each Six-Clerk should be allowed to have under him. Soon after this the Six Clerks, instead of taking clients according to the clients' choice, agreed to divide the business coming from time to time into court among themselves alphabetically. This arrangement shows that the scheme of a limited number of legalised attorneys for the Court of Chancery had now entirely ceased to operate, and had been converted into a mere legal pretext to enable these officers to tax all who were driven to such Chancery Court for justice. This regulation for dividing the business was, after some years, set aside on petition of the Master of the Rolls to the crown, as a monopoly and a breach of the liberty of the subject. In 1630 the office of Six-Clerk was, if not a sinecure, at least an appointment of great value. From a ridiculous story told about Sir Julius Cæsar, the Master of the Rolls, in Clarendon's 'Rebellion,' it appears that the appointment at that time sold for so large a sum as 6000*l.* About this time the under or sworn clerks, or clerks in court (for all these names apply to them), began to be frequently mentioned in the orders regulating the court, and soon grew into a very important body. The under-clerks were the parties who knew the merits of the different causes, and were interested in getting the work done, so as to gain the fees from the clients. The Six Clerks had begun to sink into the lethargy of sinecurists. Many orders were made to spur them into activity, but all in vain.

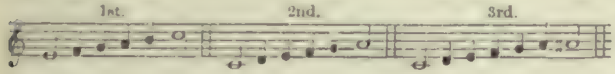
The Six Clerks, in a paper given in by them to the Chancery Commissioners of 1825, state that, "From the first establishment of the Six Clerks, up to the rebellion in the reign of King Charles I., many other important duties were attached to their office. During the usurpation, however, a part of the duties was assigned to certain new officers entitled the sworn clerks, who have ever since continued the execution thereof." The Six Clerks in this statement have fixed rather too early a date to the legal transfer. Great efforts were made for reform of legal procedure during the Commonwealth. Among others there was an ordinance for abolishing the office of Six-Clerk in 1654, but it terminated, with the other ordinances of the Commonwealth, at the Restoration, and the judges endeavoured vigorously to reinstate the Six Clerks in their old position. Lord Clarendon, in 1665, limited the under-clerks to twelve to each Six-Clerk; these under-clerks are sometimes referred to incidentally as the "attorneys of the parties," though it is strongly repeated that "the Six Clerks are the only attorneys of this court." In 1668 the Six Clerks submitted to their fate; an order was made fully recognising the under-clerks, and dividing the office-fees between them and the Six Clerks. The Six Clerks, having secured their own monopoly, had, by the year 1688, become the aggressors, and had schemed to increase their income by admitting other persons, as well as the sworn or under-clerks, to practise in their names. This was a bone of contention for many years. Before 1693 the under-clerks had obtained the privilege of filling up all the vacancies in the office by taking articled clerks themselves. From this time till their abolition, the office of Six-Clerk became a complete sinecure, and the Six Clerks were only mentioned in the court's annals with respect to the fees that they are entitled to demand from suitors. The office was abolished by Lord Brougham's Act, which enacted that vacancies should not be filled up till the number of Six Clerks was reduced to two. Nearly the same story has to be told over again with reference to the sworn clerks. For a long time these under-clerks were the principal solicitors of the court; and until the middle of the last century the chief business of the court was transacted by them without the intervention of a solicitor. The same principle of monopoly led with them to nearly the results that it did with their titular superiors. A vested right to fees in the various stages of equity proceedings brought about an inattention to business, which has led to the transfer of the prosecution of suits to the solicitors.

An effort was made in 1825 to get the offices of Six-Clerk and clerk in court abolished. It was broadly stated at this time by a solicitor of celebrity, that Mr. S. (a gentleman whose mind had failed him) was "quite as good a clerk in court after he was a lunatic;" and the expense of the office to the suitor was insisted on. Lord Eldon, however, saw no reason to interfere with these offices, and they remained condemned by the unanimous voice of the whole profession for many years longer. Ultimately they were abolished, the then holders of the offices receiving compensations so extravagant, that frequent attempts have been made, though unsuccessfully, to reopen the question.

For further information as to this office, the reader is referred to the case "Ex parte the Six Clerks," 3 Vesey's 'Reports,' 519; to the 'Reports of the Commissioners on the Offices of Courts of Justice' of 1816; to the 'Report of 1825 of the Chancery Commission;' to Beames's 'Orders of the Court of Chancery'; to pamphlets by Mr. Spence, Mr. Field, Mr. Merivale, and Mr. Wainewright; and to a powerful speech on Equity Reform, made in the end of the session of 1840, by Mr. Pemberton (now Lord Kingsdown), which was afterwards published in a separate form.

SIXTH, a musical interval, a concord, the ratio of which is 5 : 3. [CONCORD; HARMONY.]

Of the Sixth there are three kinds: the *Minor Sixth*, the *Major Sixth*, and the *Extreme Sharp Sixth*. The first (E, C), is composed of three tones and two semitones; the second (C, A), of four tones and one semitone; the third (C, A♯), of four tones and two semitones. Ex. :—



SIZAR, a term used in the University of Cambridge for a class of students who are admitted on easier terms as to pecuniary matters than others. These pecuniary advantages arise from different sources in different colleges, and are of different value. Originally certain duties were required of the students so admitted approaching to the character of menial, but these have been long discontinued. A similar class of students at Oxford are called Servitors. The word Sizar is supposed to be derived from *size*, which is used in the University to denote an allowance of provisions at the college buttery; and that from the verb to *assize*, which is much the same as the modern *assess*, which means *apportion*.

SIZE. [GLUE MANUFACTURE.]

SKEW-BACK, in civil engineering, the course of masonry forming the abutment for the voussoirs of a segmental arch, or, in iron bridges, for the ribs. In the latter case a plate of cast-iron is usually laid upon the stone skew-backs, extending the whole width of the bridge, and forming a tie to the masonry. On account of the expansion and contraction of iron under changes of temperature, the ribs should not, especially in large arches, be fixed to their abutments. The ribs of Southwark Bridge, over the Thames, were originally bolted to the masonry of the piers; but it was found necessary, on this account, to detach them, during the progress of the works.

SKEW-BRIDGE, a bridge in which the passages over and under the arch intersect each other obliquely. In conducting a road or railway through a district in which there are many natural or artificial water-courses, or in making a canal through a country in which roads are frequent, such intersections very often occur. As, however, the construction of an oblique or skew arch is more difficult than that of one built at right angles, skew-bridges were seldom erected before the general introduction of railways; it being more usual to build the bridge at right angles, and to divert the course of the road or of the stream to accommodate it, as represented in *fig.* 1, in which *a b* is a stream crossed by the road, the general direction of which is indicated by the dotted line *c d*. In a railway, and sometimes in a common road or a canal, such a deviation from the straight line of direction is inadmissible, and it therefore becomes necessary to build the bridge obliquely, as represented in the plan, *fig.* 2. Where space and neatness do not require to be considered, an oblique arch may be avoided, either by building the bridge square with the upper passage, and making the span so wide as to allow the stream to pass under it without being diverted; or by building the arch square with the stream, and of sufficient length to allow the upper passage to take an oblique course over it; but either of these is a clumsy expedient, although well adapted for some situations. The arches or tunnels by which the North-Western railway is conducted under the Hampstead Road and Park Street, near the London terminus, are instances of the latter kind of construction; the length of the arches being such that they present faces square with the line of railway, notwithstanding the oblique direction of the roads over them. A similar case occurs at Denbigh Hall, on the same line, where the railway crosses over the London and Holyhead road at such an angle that the difference of direction is only 25°. In this case a long gallery is constructed under the railway, consisting of iron ribs or girders, resting upon walls built parallel with the turnpike road; the ribs, and consequently the faces of the bridge, being at right angles with it. This gallery is about two hundred feet long and thirty-four feet wide; and by its adoption, the necessity of building an oblique arch of eighty feet span was avoided. The necessity of increasing the span of an arch according to its degree of obliquity, by which the expense and difficulty are materially increased, is illustrated by *fig.* 3, the ground-plan of an oblique arch across a stream *a b*. Here it is evident that *c g* is the actual span of the arch; although *c d*, the breadth of the stream, would be the span of a straight arch, leaving the same width of passage underneath.

Fig. 1.

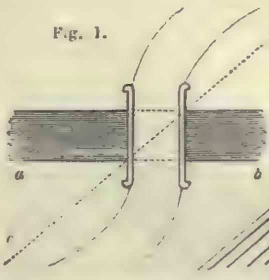


Fig. 2.

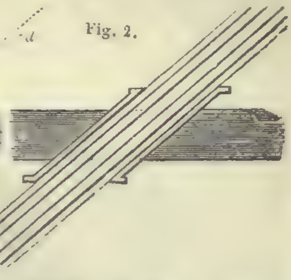

Fig. 3.

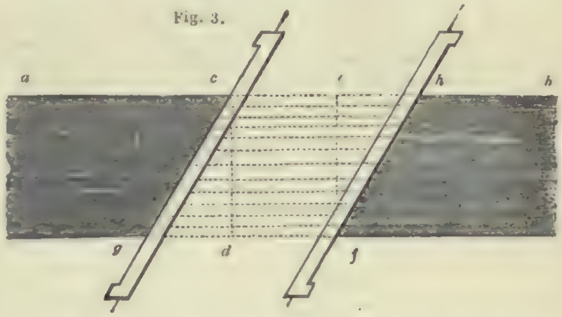
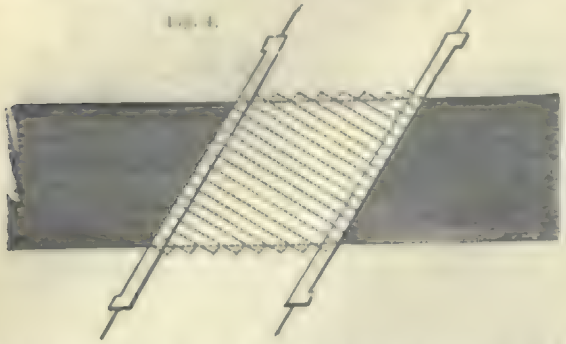


Very little is known respecting the origin of skew-bridges. It has been repeatedly asserted that those built by George Stephenson on the Liverpool and Manchester railway were the first erections of the kind; but this is certainly incorrect, there being some of earlier date even in Lancashire. A paper in the 'Transactions of the Institution of Civil Engineers,' vol i., p. 185, alludes to an oblique arch erected about the year 1530 by Nicolò, called "Il Tribolo," over the river Mugnone, near Porta Sangallo, at Florence. It appears however that the principle upon which such bridges should be constructed was too little understood to render an attempt at constructing them on a large scale advisable. The next information the writer has met with on the subject is contained in the article 'Oblique Arches,' in Rees's 'Cyclopædia;' an article which appears to have escaped the notice of modern writers on this branch of engineering science. It is written by an engineer named Chapman, who mentions oblique bridges as being in use prior to 1787, when he introduced a great improvement in their construction. Down to that time, as far as he was informed, such bridges had always been built in the same way as common square arches, the voussoirs being laid in courses parallel with the abutments. How very defective such an arch would be may be seen by reference to *fig.* 3, in which lines are drawn to indicate the direction of the courses. It is evident that here the portion *c d f e* is the only part of the arch supported by the abutments; the triangular portions *c d g* and *e f h* being sustained merely by the mortar, aided by being bonded with the rest of the masonry. This plan could therefore only be adopted for bridges of very slight obliquity, and even then with considerable risk. About the time mentioned above, Mr. Chapman was employed as engineer to the Kildare canal, a branch from the Grand Canal of Ireland to the town of Naas, on which it was desired to avoid diverting certain roads which had to be crossed. He was therefore led to look for some method of constructing oblique arches upon a sound principle, of which he considered that the leading feature must be that the joints of the voussoirs, whether of brick or stone, should be rectangular with the abutment, instead of being parallel with the face of the arch. Thus the courses, instead of taking the direction shown in *fig.* 3, were laid in the manner indicated in *fig.* 4. One of the first bridges built on this plan, the Finlay bridge, near Naas, crossed the canal at an angle of only 39°; the oblique span being 25 feet, and the height of the arch 5 feet 6 inches. Mr. Chapman observes that the lines on which the beds of the voussoirs lie are obviously spiral lines, and to this circumstance may be attributed much of the singular appearance of oblique arches. The Finlay bridge stood well, but the ingenious designer did not think it prudent in any other case to attempt so great a degree of obliquity, although he built several other bridges on the same principle, over the Grand Canal in Ireland, and over some wide drains in the East Riding of Yorkshire. He recommends carrying up the masonry as equally as possible from each abutment, in order to avoid unequal strains on the centering.

Fig. 4.

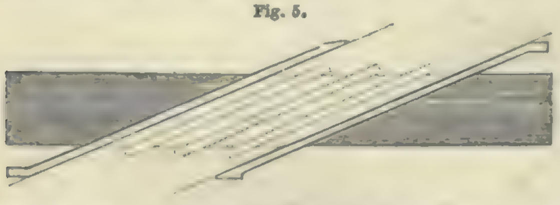


On the Liverpool and Manchester railway, out of rather more than sixty bridges, about one-fourth were built on the skew; one, built of stone, conducting the turnpike-road across the line at Rainhill, being at an angle of only 34°, by which the width of span is increased from 30 feet, the width of the railway from wall to wall, to 54 feet, the width on the oblique face of the arch. Skew-bridges have since become very common, and some have been erected of even greater obliquity. That at Box-moor, on the London and North-Western railway, was for long unrivalled for obliquity by any other brick arch. Its angle is 32°, the square span 21 feet, and the oblique span 39 feet. There are also brick arches of great obliquity on the Greenwich and Blackwall railways, but with their precise angles we are unacquainted; on the Paris and Rouen railway there is a skew-bridge of brickwork with stone bond courses of 28° of obliquity.

From Mr. Buck's treatise on oblique bridges, it appears that the difficulty of building skew-bridges increases with the obliquity of the angle from 90° to 45°, which is supposed to be the most hazardous angle for a semicircular arch; but that beyond that point, instead of increasing, it rather diminishes to about 25°, which appears to be about the natural limit for a semi-cylindrical arch. Mr. Buck, whose experience renders his opinion highly valuable, considers that oblique arches of the elliptical form should not be attempted, as they are deficient in stability, more difficult to execute, and more expensive than semicircular or segmental arches.

The construction of skew-bridges of iron or timber is comparatively simple, the ribs or girders of which such bridges are composed being of the usual construction, laid parallel with each other, but the end of each being in advance of that next preceding it. *Fig.* 5 represents the ground-plan of such a bridge, the dotted lines indicating the situation of the ribs upon which the platform is supported. The extraordinary iron bridge by which the Manchester and Birmingham railway is conducted over Fairfield-street, Manchester, at an angle of only 24½°, is a fine example of this kind of skew-bridge. It consists of six ribs, of rather more than 128 feet span, although the width of the street is only 48 feet, resting upon very massive abutments of masonry. The total weight of iron in this bridge, which is considered to be one of the finest iron arches ever built, is 540 tons. It was erected from the design of Mr. Buck, who has constructed several other oblique bridges of great size and very acute angles. Timber bridges, formed of trussed ribs or girders, are built on the same principle. One of very great obliquity, on the Sechill railway, is represented in the second series of Brees's 'Railway Practice.' A somewhat similar mode of constructing skew-bridges in brickwork was introduced by Mr. Gibbs on the Croydon railway. The Jolly Sailor bridge, which crosses over this line near Norwood, consisted originally of four separate ribs of brickwork, each forming an elliptical arch of 50 feet span, with a versed sine of 12 feet 6 inches, supporting a flat viaduct of Yorkshire flagstones. Each of these ribs, which were three feet wide on the transverse face, was built square, so that the brickwork was of the simplest kind; but by making the respective abutments project beyond each other according to the oblique direction of the railway, the ribs, taken collectively formed a skew-arch. In a bridge erected by Mr. Woodhouse on the line of the Midland Counties railway, the same principle is adopted, but the ribs are placed close together, so that no platform of flagstones is required.

Fig. 5.



SKIN, DISEASES OF. Most of the diseases of the skin are described in this work under their particular names. In this article we shall supply an arrangement of them, and a description of those which are not described under special heads. The following arrangement is that adopted by Rayer in his work on diseases of the skin:—

Class I. Inflammation of the Skin.

Order 1. *Exanthematous.*—Rubeola, Roseola, Scarlatina, Urticaria, Erythema, Erysipelas.
Order 2. *Bullous.*—Vesication, Ampullæ, Pemphigus, Rupia, Zona.
Order 3. *Vesiculous.*—Herpes, Psora, Eczema, Miliaria.
Order 4. *Pustulous.*—Varicella, Variola, Vaccinia, Vaccinella, Ecthyma, Cuperosa or Acne, Mentagra, Impetigo, Tinea, Artificial pustules.
Order 5. *Furunculous.*—Hordeolum, Furuncle, Anthrax.
Order 6. *Papulous.*—Strophulus, Lichen, Prurigo.
Order 7. *Tuberculous.*—Lupus, Cancer, Elephantiasis of the Greeks.
Order 8. *Squamous.*—Lepra, Psoriasis, Pityriasis [Scurf].
Order 9. *Linear.*—Fissures.
Order 10. *Gangrenous.*—Malign pustules, Carbuncle of plague.
Order 11. *Multiform.*—Burns, Frost-bite, Syphilitic eruptions.

Class II. Cutaneous and Subcutaneous Congestions, and Hæmorrhages.

Cyanosis, Vibices, Petechiæ, Purpura Hæmorrhagica, Ecchymosis, Dermatorrhagia.

Class III. Nervous Diseases of the Skin.

Exaltation, Diminution, Abolition of the sensibility of the skin, without appreciable alteration in the texture of this membrane.

Class IV. Alterations in the Colour of the Skin.

Order 1. *Decoloration.*—Leucopathia, partial, general; Chlorosis.
Order 2. *Accidental Colorations.*—Ephelis, Lentigo, Chloasma, Meladermis, Icterus, Nævus maculosus, Argentism.

Class V. Morbid Secretions.

Ephidrosis, Acne, Folliculous Tumours.

Class VI. Defects of Conformation and Texture.

Distention of the Skin, Cicatrices, Vegetations, Nævus hæmatodes, Subcutaneous vascular tumours, warts, pearly granulations; Corns, Ichthyosis, Horny appendages.

Diseases of the skin are very numerous and prevalent, but in the case of the majority which occur they arise from the neglect of some of the conditions necessary for the health of the skin. These conditions in general are, good nutritious food, which should be properly digested; a due amount of warm clothing, especially during changeable and cold weather; constant and regular exercise, so as to keep the skin as an excretory organ in perfect order; and daily ablution of every part of the body, without which and the occasional use of soap it is vain to expect to be free from many forms of skin disease.

The following are the diseases which appear to demand further notice:—

Eczema, Heat-eruption, is an inflammation of the skin, characterised at the outset by small non-contagious vesicles, the fluid of which is finally reabsorbed; by superficial excoriations, attended by a serous discharge, or by a squamous condition of the skin. This disease may be confined to one particular part of the body, or it may attack the whole surface. It may arise from a local cause, as from the direct rays of the sun, or from some general disturbance of the system. The vesicles may be only few, and the surrounding skin only slightly inflamed and confined to a very limited surface, or the vesicles may be numerous, the excoriations painful, the surface attacked extensive, and the tendency to inflammatory action in the skin so strong as to produce pustules instead of vesicles. Such are the characters of the three forms of eczema usually described by writers on diseases of the skin.—*E. solaris*, *E. rubrum*, *E. impetiginoides*. Eczema is more likely to be confounded with itch than any other disease, from which it may be distinguished by its non-contagiousness and the very different parts of the tegumentary system which it occupies.

There is a form of eczema which comes on from the exhibition of mercury and the external application of other medicines, and which frequently arises from the carelessness of the person attacked, which is called *E. mercuriale*.

The treatment of eczema must be adapted to the causes which have produced it. According to the general state of health of the person attacked, the disease will be either acute or chronic. Slight cases of acute eczema require only a simple treatment; a light diet, saline purgatives, and cooling or emollient applications to the part being all that is required. In some cases the inflammation is great and the pain intense, and where this occurs bleeding and a more active general treatment should be had recourse to. Chronic eczema is much more difficult to treat. The general health demands attention, and alteratives and tonics, according to circumstances, are demanded. Astringent lotions and ointments, such as the preparations of silver, zinc, alum, &c., may be used; sulphurous baths, and various mineral waters have also been recommended in old chronic cases of this disease. The tincture of cantharides and the preparations of arsenic have also been employed in the chronic forms of eczema.

Miliaria (Febris miliaris, Miliary Eruption) is also a vesiculous disease of the skin, and is described as contagious. It is accompanied with inflammation of the gastro-intestinal mucous membrane, and is accompanied by profuse sweating. Miliaria as an epidemic and independent disease is only seen between the 43rd and 49th degrees of latitude, and its existence has been doubted by some nosologists. It frequently accompanies other diseases, and retires with the cessation of the disease which it attends. When the fever accompanying it is slight it requires little treatment. Gentle purgatives and demulcents will be found sufficient. In the epidemic form, however, it is often a formidable disease, and requires the same treatment as other epidemic contagious fevers.

Rupia is a bullous disease accompanied with small bullæ, the bases of which are inflamed. The bullæ are not numerous but flat and full of a serous fluid, which becomes thick, puriform, or sanguinolent, and drying up forms blackish thin or prominent crusts. It is commonly developed on the legs, sometimes on the loins or thighs. It attacks children that are of a delicate constitution, and persons weakened by other diseases. The scrofulous are peculiarly liable to it, and it comes on after hard living, insufficient food exposure to cold, and vicious courses of life. It is generally indicative of an imperfect state of nutrition, and the treatment consists not so much in applications to the diseased skin, as in giving tone to the system by nutritious food, and tonic and alterative medicines.

Ecthyma (Pustulous Scale) is a non-contagious inflammation characterised by large pustules raised upon a hard circular base of a bright red colour. The pustules are of the largest size, the *phlyzaciæ* of Willan, so that ecthyma bears the same relation to pustular diseases that rupia does to vesicular ones. In some stages in fact it is difficult to distinguish one of these diseases from another. Willan describes four varieties of ecthyma, but Rayer recognises but two, acute ecthyma and chronic ecthyma. Acute ecthyma is a comparatively rare disease; it generally appears on the neck and shoulders, and runs its course in a few days. This form requires little treatment; light diet, diluent drinks, mild purgatives, and warm or cold applications to the part will suffice.

In chronic ecthyma the same kind of pustules appear, which discharge their contents in the course of two or three days, leaving behind them thick brown adherent crusts, which sometimes fall off, leaving an ulcer behind, but more frequently leaving a cicatrix. This form of the disease comes on in scrofulous and debilitated subjects, and is frequently modified by a syphilitic taint. Just in proportion to the intensity of the constitutional derangement will be the duration and extent of the disease. In its treatment the general health must be especially attended to; it is more a disease indicating a want of action than increased action, and alteratives, tonics, nutritious diet, change of air, and sea-bathing are more beneficial than the opposite kind of treatment.

Acne (Gutta rosacea, Rose-drop) is a chronic inflammation of the skin characterised by an eruption of small pustules surrounded by a hard and inflamed base. They are generally observed on the cheeks, nose, and forehead, and sometimes on the ears and neck. The pustules are sometimes single, constituting the simple form of the disease; at other times they become hardened and the whole skin becomes red, when the disease has different designations. This disease has its origin in the oil-tubes, and arises from an obstruction to the performance of their functions, which produces inflammation. The oil tubes of the face are very liable to obstruction from exposure to the air and other causes, and may be frequently observed tipped with a little black spot, and when pressed they give out a quantity of their oily secretion in the form of a little maggot. They were at one time supposed really to possess an independent animal life. Although this is not the case with the masses of oil in question, it is now known that a little acarus takes up its abode in these oil tubes, and is well known to zoologists under the name of Demodex Folliculorum. This little insect may then in some instances be the exciting cause of acne.

In the treatment of acne, regard must be had to the general health. It is frequently connected with a diseased state of the gastro-intestinal mucous system, which requires attention. Where it is connected with general debility from a rapid growth, or with a scrofulous constitution, tonics and alteratives with sea-bathing and regular exercise will be found of service. As external applications, the preparations of copper, zinc, and mercury, have been found most efficient. Where the face is much swelled and inflamed, fomentations will be of service previous to the use of the astringents.

Lichen is a papulous disease, characterised by the simultaneous or successive eruptions of red itching pimples, scattered or disposed in groups over the whole body. It is in the adult what Strophulus is in the child.

Lupus is a disease of the skin which, although it usually attacks the face, may appear on any other part of the body. It is generally attended with inflammatory action and with more or less enlargement of the parts attacked. It terminates in ulceration, which on account of its tendency to destroy the tissues which it attacks has got for this disease the name of "wolf." The ulcer is also called the "rodent ulcer," and the term *noli me tangere* has been applied to it. The disease may be superficial or it may penetrate more or less deeply, destroying whatever tissues it attacks. There is no doubt about the resemblance of this disease to cancer, especially that form called epithelial. It is, nevertheless, so strongly separated that it would be utterly inconsistent with the present knowledge of the nature of cancer to regard it as originating in the same state of the system. [CANCER.] The condition of the system and the nature of the ulceration rather point to the scrofulous diathesis as the originator of this disease.

In lupus no pathological elements can be discovered resembling those of cancer. If removed it does not recur, and there is no tendency to the production of the same disease in the lymphatics as in cancer. It is therefore a much less formidable disease. Nevertheless, the progress of the ulceration in many cases of lupus is sufficiently alarming and demands constant attention.

The treatment must be both local and general. In the local treatment removal by the knife is mostly out of the question, on account of the extent of surface involved. According to the tendency exhibited by the ulceration to spread a severe or mild system of cauterisation should be pursued. Sometimes the application of sulphate or acetate of zinc or nitrate of silver is sufficient to stimulate the parts to assume a healthy action; whilst at others more violent applications, as the chloride of zinc and tannic, nitric, or hydrochloric acids, are to be recommended. General treatment is frequently very efficacious, and this according to circumstances. In cases of tuberculosis of the system cod liver oil and quinine and iron may be used with advantage. In another set of cases arsenic has been found efficacious, whilst perhaps a larger number are benefited by preparations of iodine.

SKIN-DRESSING. [LEATHER MANUFACTURE.]

SKY is the name commonly applied to the infinite space which surrounds the earth, and of which the visible portion, above the horizon of a spectator on any part of the earth's surface, appears to have the form of a concave segment less than a hemisphere.

The earth is surrounded by the atmosphere, which is charged with vapours and terrestrial particles; and by the reflections which, in consequence, the rays of light experience in passing to the spectator, and the absorption which they undergo in their long transit of the atmosphere when the sun is near the horizon, the sky assumes the variously-coloured tints under which it is seen.

It is known from many experiments that *pure* air is devoid of colour; and the observations of M. de Saussure ('Voyages dans les Alpes,' tom. 4, p. 289) have established the fact, that, in an atmosphere free from vapours, such objects as mountains covered with snow, when seen by a spectator at a distance of 20 or 30 leagues from them, by light which is merely transmitted through the air, appear to be white: the same philosopher has observed, however, that at times when the sun is seen to set behind a mountain so covered, the blue rays reflected from the sky to the mountain, and from thence to the spectator, cause the mountain to assume a blue colour, the other light with which the mountain is illuminated not being strong enough to overpower the blue reflected rays.

When the sun has considerable elevation, the rays of light which pass through the earth's atmosphere almost perpendicularly to its surface, undergo scarcely any change of direction; but, with respect to the light from the sun which enters obliquely into the atmosphere, the violet and blue rays are partially arrested in their course, and are reflected in abundance to the earth; they thus, when the atmosphere is nearly free from clouds, give to the parts of the sky which are remote from the apparent place of the sun an azure tint.

The blue colour of the sky about the zenith increases in proportion as the sun is nearer the horizon; and, at the same time, the blue rays in the beams of light which traverse the atmosphere in directions nearly parallel to the horizon are absorbed, so that it is chiefly those of less refrangibility, such as the yellow and the red, that arrive at the eye of the spectator: in consequence of this the sky near the horizon, on the side which is towards the sun, appears to be highly tinted with those colours.

Many of the blue rays, after reflection from the upper parts of the atmosphere, are, however, absorbed in passing down to the earth; and further, it seems probable that in that portion of the reflection which takes place at a great elevation the blue rays are reflected in larger proportion compared with other colours than lower down; and hence it is that the blue tint of the sky is found to increase in intensity as the spectator ascends above the general surface of the earth. On the top of high mountains, or in balloons at great elevations, the proportion of blue rays which, after reflection in the atmosphere enter the eye is very great; and the blueness at length becomes a deep black ground on which the stars appear to shine at all times with as much lustre as at midnight on the earth, during the absence of the moon. It is hence evident that if it were not for the innumerable reflections of the light from the sun or moon, which take place in the atmosphere, total darkness would prevail from the instant of sun-set to that of sun-rise; and even during the day, darkness would ensue, so that the stars would become visible, every time that the sun is obscured by a cloud of sufficient density.

That the blue tint of the sky is caused by light reflected in the atmosphere, is abundantly evident from the fact that the light of the sky is found to be polarized, this quality in light being a result of its reflection. Sir David Brewster, who first made the observation, has moreover ascertained that the light of the sky consists of two parts, one blue and the other nearly without colour; and he discovered that these lights are polarized in different directions. ('Treatise on New Philosophical Instruments,' p. 349.)

The hypothesis that the azure colour of the sky is caused by reflections of blue rays, was at one time objected to on the ground that the shadows of opaque objects, placed on white paper and exposed to the sun's light, should always appear to be blue, since the part of the paper which is in shadow can only be visible by the light of the sky reflected from thence. This phenomenon is, in fact, frequently observed; but M. de Saussure, while admitting that he has often perceived the shadows of objects to be bluish in the mornings and evenings on the general surface of the earth, states that in Alpine regions, where the sky is intensely blue, the shadows of objects never appear to be so: he adds that, of fifty-nine observations made for the purpose of ascertaining the colours of shadows on the mountains, thirty-four showed them to be a pale violet, eighteen showed them to be black, six a pale blue, and once they appeared to be yellowish. It may be inferred, therefore, that shadows cast by opaque objects are so much affected by the colours of the neighbouring objects that a right judgment can scarcely be formed of the colour which they receive from the light of the sky. [ACCIDENTAL COLOURS.] To the like interference must be ascribed the variously-coloured shadows which were observed by M. Bouguer ('Essai d'Optique;' and M. Buffon, 'Mémoires de l'Académie des Sciences,' 1743.)

Between the tropics the transparency of the atmosphere is far greater than it is, in general, in regions beyond them towards the north or south; hence the sky there is almost always serene and intensely blue, while the clouds near the setting sun are brightly tinted with the prismatic colours. The skies of the south of Europe and some parts of North America are distinguished for their serenity and beauty; but, in these respects, they are said to be inferior to the skies over the islands in the Pacific Ocean.

For the description of an instrument invented in order to measure the intensity of the blue colour in the sky, see CYANOMETER.

SKYLIGHT. In the arts, the word *skylight* is sometimes used to express the frame or the window by which the direct light from the upper regions of the atmosphere is allowed to enter a room; at other times, and especially in cases connected with architectural jurisprudence, *skylight* is understood to mean the view of a portion of the atmosphere itself, or, in other words, an uninterrupted view of the portion of space to which a house proprietor is entitled. In this notice. attention will principally be directed to the former meaning of the word; for the latter meaning, and the various conditions attaching to it. see the articles EASEMENT, and LIGHTS, ANCIENT.

Skylights, in the ordinary sense may be divided into those which are placed in the roof or covering of the building, and into those which are placed in lanterns rising above the line of the roof; the former transmitting the light directly, the latter by means of vertical openings in their sides. In some cases. also, a building may be lighted by means of inclined skylights on the respective sides of the inclined roof over the flat ceiling of the room, and by a horizontal skylight in that ceiling; or, in other words, by a double skylight, as at the Madeleine at Paris; and in the enormous rooms of the spinning-factories a species of imperfect lantern skylight is used, in which one vertical glazed side and three obscure sides of a half pyramid are introduced. Small vertical windows, or, as they are technically called, "dormers," are occasionally used for the purpose of lighting domical or other buildings from the sky; but, strictly speaking, they must come under the category of windows. The hall of the Middle Temple of London, the dome of St. Paul's, and the Law Courts at Westminster, are illustrations of the use of lantern lights; the Pantheon at Rome. and the Pantheon in Oxford Street, London, are illustrations of the use of simple skylights; the other classes of skylights are principally used in commercial or manufacturing establishments, although the double ones are susceptible of being treated so as to produce very striking architectural effects. In mediæval structures, such as Westminster Hall, a portion of the light is obtained from the sky by means of dormers; but clerestory windows are much more frequently resorted to in the buildings of this period, when all the light cannot be obtained from the lower side walls.

The practical advantages of the respective kinds of skylights seem to be as follows:—In lantern lights, it is easy to provide for effecting ventilation at the same time and by the same means as those used for the admission of light. The windows in these cases are on the vertical sides of the lantern, and the top is covered by an opaque roof, usually formed of imperfectly conducting materials; any condensation of moisture from the internal atmosphere takes place, under these circumstances, on the vertical glass of the sides, and it can thence be easily removed. Skylights placed on the slope or at the top of a roof are exposed to considerable inconvenience from the condensation thus alluded to; and if they must be resorted to, it should be the object of the architect to keep them within the width susceptible of being covered by one sheet of glass; because if the length of the panes be such as to require the use of two sheets, the drops of water arising from condensation are likely to accumulate at the line of junction, and either to fall from thence or to remain under the lap, and if a frost should occur whilst water is there, it is very probable that the expansion of the water passing into ice may crack the glass. The introduction, by Sir J. Paxton, of the ridge and furrow system, has enabled modern architects to execute large plane surfaces of skylight; and it has, moreover, the advantage of being equally applicable to lantern or to flat lights of this description. Lantern lights must, it may be added, be placed upon the axis of the roof covering the room so lighted; skylights may be placed wherever it may be desired so to do; and in the large domes of modern buildings it is found that the lanterns are invariably placed over their centres, whilst the skylights let into the sides of roofs are disposed in the panels or segmental divisions in such wise as to cause the light to fall in the desired manner on the side walls. Lanterns diffuse light more equally over the areas they serve than lights let into the sides of the roof, but not more so than central skylights, such as those of the Pantheon; and for this reason it seems that, in sculpture galleries lighted from above, it would be preferable to introduce lanterns; whilst in picture galleries plane skylights on the slopes of the roof are the most advantageous, provided always that they do not receive the direct rays of the sun.

There are, indeed, few positions in which it is desirable to admit the sun's rays in rooms lighted from above; and wherever it is possible so to do, the light should be admitted from the north exclusively, because the glare and the reflection of the sun's rays affects the purity of colour of the objects exposed to them. In factories, and in show rooms, this law of excluding the direct sun's rays is carefully observed, and the skylights formed over them are usually made of the form above described; that is to say, as a section of a square pyramid, receiving light from its base which faces the north. The proportion of the surface for the transmission of light to the opaque part of the ceiling should be at least as 1 : 20; for in the Pantheon the diameter of the rotunda is about 141 feet, and that of the central light is 30 feet (or in the ratio of their areas as 1 to 22 nearly), and the light in that building would not be sufficient for the purposes of commerce or of manufacture. The height of the room will, however, affect this consideration; for the pencil of rays admitted through the skylight must be able to reach every portion of the inclosed area, and in a well-lighted room there should be no necessity for trusting to reflected rays. In the Pantheon, the height from the floor to the under side of the skylight is precisely equal to the diameter of the rotunda; and Fontana, in his 'Descrizione del Tempio Vaticano,' states that an examination of the most important buildings lighted by lanterns showed that the best proportions of the diameters of those structures to the diameters of the cupolas on which they rested were as 1 to 6, and that the height of such lanterns should be equal to half the diameter of the cupola; the whole of this height is not, however, devoted to the glazed part of the structure.

SLAKED LIME. [CALCIUM.]

SLANDER consists in the malicious speaking of such words as render the party who speaks them in the hearing of others liable to an action at the suit of the party to whom they apply. The mere speaking of the defamatory words instead of the writing of them is that which constitutes the difference between libel and slander. [LIBEL.]

Slander is of two kinds: one, which is actionable, as necessarily importing some general damage to the party who is slandered; the other, which is only actionable where it has actually caused some special damage. The first kind includes all such words as impute to a party the commission of some crime or misdemeanor for which he might legally be convicted and suffer punishment, as where one asserts that another has committed treason, or felony, or perjury. It also includes such words spoken of a party, with reference to his office, profession, or trade, as impute to him malpractice, incompetence, or bankruptcy; as of a magistrate, that he is partial, or corrupt; of a clergyman, that "he preaches lies in the pulpit;" of a barrister, that "he is a dunce, and will get nothing by the law;" and so on: or that tend to the disherison of a party, as where it is said of one who holds lands by descent, that he is illegitimate. Where a party is in possession of lands which he desires to sell, he may maintain an action against any one who slanders his title to the lands; as by stating that he is not the owner. With respect to the second kind of slander, the law will not allow damage to be inferred from words which are not in themselves actionable, even although the words are untrue and spoken maliciously. But if, in consequence of such words being so spoken, a party has actually sustained some injury, he may maintain an action of slander against the person who has uttered them. In such case the injury must be some certain actual loss, and it must also arise as a natural and lawful consequence of speaking the words. No unlawful act done by a third person, although he really was moved to do it by the words spoken, is such an injury as a party can recover for in this action. Thus, the loss of the society and entertainment of friends, of an appointment to some office, the breach of a marriage engagement caused by the slanderer's statement, are injuries for which a party may recover damages. But he can have no action because in consequence of such statement certain persons, to use an illustration of Lord Ellenborough's, "have thrown him into a horsepond by way of punishment for his supposed transgression."

With respect to both kinds of slander, it is immaterial in what way the charge is conveyed, whether by direct statement, or obliquely, as by question, epithet, or exclamation.

Two cannot join in bringing one action of slander, except in the case of husband and wife, or of partners for an injury done to their joint trade; nor can an action be brought against two, except a husband and wife, where slanderous words have been spoken by the wife.

In answer to an action of slander the defendant may plead that the words spoken were true, or that they were spoken in the course of a trial in a court of justice, and were pertinent to the case; or formed the subject of a confidential communication, as where a party on application *bonâ fide* states what he believes to be true relative to the character of a servant, or makes known facts merely for the purpose of honestly warning another in whom he is interested. (Com., *Dig.*, 'Action on the Case for Defamation,' D. 1, &c.)

SLATE-WORKING. Referring to SLATE, in NAT. HIST. DIV., for an account of the geological formation and structure of this valuable rock, we here add a few words concerning its practical working.

The quarrying of slate is comparatively easy, seeing that the lamellated structure enables the substance to split easily into layers. The usual processes are adopted for sawing and smoothing the slabs; but improved machines for these purposes have been introduced within the last few years. One machine has been invented for hollowing out thick blocks of slate into sinks and vessels, by means of cutters screwed to the ends of revolving shafts. By the use of peculiar tools, slate is now turned in the lathe. Mr. Mathews's apparatus for cutting and dressing slate consists of a frame, provided with arms, cutters, levers, toothed wheels, &c., in such a way that the cutters may be raised by a lever, and let fall with a sudden blow; and this in such a manner as to work the slate either into plain or fancy surfaces. Ordinary slate cannot very well be polished like other kinds of hard stone; it is rubbed smooth with an iron plate, sand, or gritstone, and water. Within the last quarter of a century, there has been a tendency to use slate for many purposes for which other substances used to be employed. The slate top of a billiard table is perhaps the best kind of work in this material. The best tables measure 12 feet by 6 feet; the top consists of four slabs of slate 6 feet by 3 feet, and one inch thick, ground on the lower surface planed on the upper, and adjusted edge to edge with the most scrupulous care. Pavements, cisterns, walls, partitions, &c., are now largely made in this material. "Enamelled slate" is used for table tops, chimney pieces, wash-stand tops, columns, pilasters, door furniture, monuments, mural tablets, &c.

What are called slate *pencils* are simply narrow slips of a soft kind of slate. Some of them are made to slide in wooden tubes or holders, by a propelling apparatus similar in character to that of certain of the ever-pointed pencils. Artificial slate pencils have been introduced, made of a mixture of alumina, French chalk, and soapstone.

The largest slate quarries in the United Kingdom are the Penrhyn, belonging to Colonel Pennant. These are briefly noticed under BANGOR, in GEOG. DIV.

M. Raphael Carmana has recently proposed the use of slate as a substitute for box-wood in wood engraving. He states that it is easily penetrated by the graver; that the finest lines are producible; and that slate is more durable than box under the action of the printing-press.

SLAVE, SLAVERY, SLAVE-TRADE. The word slavery has various acceptations, but its complete meaning is the condition of an individual who is the property of another or others. Such was the condition of the "servi," or slaves among the Romans and Greeks; such is still that of the slaves in Eastern countries, and that of the negro slaves in many parts of Africa and America. A mitigated form of this condition has existed up to the present time in the case of the serfs in Russia and Poland, though in the former, at least, it is about to be abolished; and still exists among a similar class in India and some other parts of Asia. The Russian and Polish serf is bound to the soil on which he is born; he may be sold or let with it, but cannot be sold away from it without his consent; he is obliged to work three or four days a-week for his master, who allows him a piece of land, which he cultivates. He can marry, and his wife and children are under his authority till they are of age. He can bequeath his chattels and savings at his death. His life is protected by the law. The slave of the Greek and Roman nations had none of these advantages, any more than the negro slave of our own times; he was bought and sold in the market, and was transferred at his owner's pleasure; he could acquire no property; all that he had was his master's; all the produce of his labour belonged to his master, who could inflict corporeal punishment upon him; he could not marry; and if he cohabited with a woman, he could be separated from her and his children at any time, and the woman and children sold. The distinction therefore between the slave and the serf is essential. The villeins (villani) of the middle ages were a kind of serfs, but their condition seems to have varied considerably according to times and localities. In the present article we treat only of the real slave of ancient and modern times.

Slavery, properly so called, appears to have been, from the earliest ages, the condition of a large proportion of mankind in almost every country, until times comparatively recent, when it has been gradually abolished by all Christian states, at least in Europe. The condition of slavery constitutes one great difference between ancient and modern society. Slavery existed among the Jews; it existed before Moses, in the time of the Patriarchs; and it existed, and still continues to exist, in many parts of Asia. The "servants" mentioned in Scripture history were mostly slaves: they were strangers, either taken prisoners in war or purchased from the neighbouring nations. They and their offspring were the property of their masters, who could sell them, and inflict upon them corporeal punishment, and even in some cases put them to death. But the Hebrews had also slaves of their own nation. These were men who sold themselves through poverty, or they were insolvent debtors, or men who had committed a theft, and had not the means of making restitution as required by the law, which was to double the amount, and in some cases much more. (Exod. xxii.) Not only the person of the debtor was liable to the claims of the creditor, but his right extended also to the debtor's wife and children. Moses regulated the condition of slavery. He drew a wide distinction between the alien slave and the native servant. The latter could not be a perpetual bondman, but might be redeemed; and if not redeemed, he became free on the completion of the seventh year of his servitude. Again, every fifty years the jubilee caused a general emancipation of all native servants.

The sources of the supply of slaves have been the same both in ancient and modern times. In ancient times all prisoners were reduced to slavery, being either distributed among the officers and men of the conquering army, or sold. When the early Æolian and Ionian colonies settled in the islands of the Ægean Sea, and on the coast of Asia Minor, it was a frequent practice with them to kill the adult males of the aboriginal population, and to keep the women and children. As, however, dealing in slaves became a profitable trade, the vanquished, instead of being killed, were sold, and this was so far an improvement. Another source of slavery was the practice of kidnapping men and women, especially young persons, who were seized on the coast, or enticed on board by the crews of piratical vessels. The Phœnicians, and the Etruscans or Tyrrhenians, had the character of being men-stealers; and also the Cretans, Cilicians, Rhodians and other maritime states. Another source was, sale of men, either by themselves, through poverty and distress, or by their relatives and superiors, as is done now by the petty African chiefs, who sell not only their prisoners, but their own subjects, and even their children, to the slave-dealers. Herodotus (v. 6) states that some of the Thracian tribes sold their children to foreign dealers.

Among the Greeks slavery existed from the heroic times, and the purchase and use of slaves are repeatedly mentioned by Homer. The labours of husbandry were performed in some instances by poor freemen for hire, but in most places, especially in the Doric states, by a class of bondmen, the descendants of the older inhabitants of the country, resembling the serfs of the middle ages, who lived upon and cultivated the lands which the conquering race had appropriated to themselves; they paid a rent to the respective proprietors, whom they also attended in war. They could not be put to death without trial, nor be sold out of the country, nor separated from their families; they could acquire property, and were often richer than their masters. Such were the Clarotæ of Crete, the Penestæ of Thessaly Proper, and the Helots of Sparta, who must not be confounded with the Periœci, or country inhabitants of Laconica in general, who were political subjects of the Doric community of Sparta, without however being bondmen. In the colonies of the Dorians beyond the limits of Greece, the condition of the conquered natives was often more degraded than that of the bondmen of the parent states, because the former were not Greeks, but barbarians, and they were reduced to the condition of slaves. Such was the case of the Kallirioi or Kallikurioi of Syracuse, and of the native Bithynians at Byzantium. At Heraclea in Pontus, the Mariandyni submitted to the Greeks on condition that they should not be sold beyond the borders, and that they should pay a fixed tribute to the ruling race.

The Doric states of Greece had few purchased slaves, but Athens, Corinth, and other commercial states had a large number, who were mostly natives of barbarous countries. The slave population in Attica has been variously estimated as to numbers, and it varied of course considerably at different periods; but it appears that in Athens, at least in the time of its greatest power, they were much more numerous than the freemen. From a fragment of Hyperides preserved by Suidas (*v.* ἀπεψηφίσατο), the number of slaves appears to have been at one time 150,000, who were employed in the fields and mines of Attica alone. Even the poorer citizens had a slave for their household affairs. The wealthier citizens had as many as fifty slaves to each family, and some had more. We read of philosophers keeping ten slaves. There were private slaves belonging to families, and public slaves belonging to the community or state. The latter were employed on board the fleet in the docks and arsenal, and in the construction of public buildings and roads.

Slaves were dealt with like any other property: they worked either on their master's account or on their own, in which latter case they paid a certain sum to their master; or they were let out on hire as servants or workmen, or sent to serve in the navy of the state, the master receiving payment for their services. Mines were worked by slaves, some of whom belonged to the lessees of the mine, and the rest were hired from the great slave proprietors, to whom the lessees paid a rent of so much a head, besides providing for the maintenance of the slave, which was no great matter. They worked in chains, and many of them died from the effect of the unwholesome atmosphere. Nicias the elder had 1000 slaves in the mines of Laurium; others had several hundreds, whom they let to the contractors for an obolus a-day each. At one time the mining slaves of Attica murdered their guards, took possession of the fortifications of Sunium, and ravaged the surrounding country. (Fragment of Posidonius's Continuation of Polybius; see Boeckh's 'Public Economy of Athens,' b. i.) The thirty-two or thirty-three iron-workers or sword-cutlers of Demosthenes annually produced a net profit of thirty minæ, their purchase value being 190 minæ; whilst his twenty chair-makers, whose value was estimated at 40 minæ, brought in a net profit of 12 minæ. (Demosthenes 'Against Aphobus,' i.)

The ancients were so habituated to the sight of slavery, that none of the Greek philosophers make any objection to its existence. Plato, in his 'Perfect State,' desires only that no Greeks should be made slaves.

The Etruscans and other ancient Italian nations had slaves, as is proved by those of Vulsinii revolting againt their masters, and by the tradition that the Bruttii were runaway slaves of the Lucanians. The Campanians had both slaves and gladiators previous to the Roman conquest. But the Romans, by their system of continual war, caused an enormous influx of slaves into Italy, where the slave population at last nearly superseded the free labourers.

The Roman system of slavery had peculiarities which distinguished it from that of Greece. The Greeks considered slavery to be founded on permanent diversities in the races of men. (Aristotle, 'Polit.,' i. 5.) The Romans admitted in principle that all men were originally free ('Instit.,' i., tit. 2) by natural law (jure naturali), and they ascribed the power of masters over their slaves entirely to the will of society, to the "jus gentium," if the slaves were captives taken in war, whom the conquerors, instead of killing them, as they might have done, spared for the purpose of selling them, or to the "jus civile," when a man of full age sold himself. It was a rule of Roman law, that the offspring of a slave woman followed the condition of the mother. ('Instit.,' i., tit. 3.) Emancipation was much more frequent at Rome than in Greece: the emancipated slave became a freedman (libertus), but whether he became a Roman citizen, a Latinus, or a Dediticius, depended on circumstances. If the manumitted slave was above thirty years of age, if he was the Quiritarian property of his manumittor, and if he was manumitted in due form, he became a Roman citizen. (Gaius, i. 17.) At Athens, on the contrary, emancipation from the dominion of the master was seldom followed by the privileges of citizenship even to a limited extent, and these privileges could only be conferred by public authority. It is true, that at Rome, under the empire, from the enactment of the Lex Ælia Sentia, passed in the time of Augustus, there were restrictions, in point of number, upon the master's power of freeing his bondmen and raising them to the rank of Roman citizens; still in every age there was a prospect to the slave of being able to obtain his freedom.

Slaves were not considered members of the community: they had no rights, and were in most respects considered as things or chattels. They could neither sue nor be sued. When an alleged slave claimed his freedom on the plea of unjust detention, he was obliged to have a free protector, to sue for him, until Justinian ('Code,' vii., tit. 1, 7, 'De adsertione tollenda') dispensed with that formality. Slaves had no connubium, that is, they could not contract a Roman marriage; their union with a person of their own rank was styled contubernium; and even the Christian church for several centuries did not declare the validity of slave marriages. At last the Emperor Basilius allowed slaves to marry and receive the blessing of the priest, and Alexius Comnenus renewed the permission. As slaves had no connubium, they had not the parental power (patria potestas) over their offspring, no ties of blood were recognised among them, except with respect to incest and parricide, which were considered as crimes by the law of nature. Though slaves were incapable of holding property, they were not incapacitated from acquiring property, but what they did acquire belonged to their masters. They were allowed to enjoy property as their own, "peculium," consisting sometimes of other slaves; but they held it only by permission, and any legal proceedings connected with it could only be conducted in the name of the master, who was the only legal proprietor. Until the latter period of the republic, slaves, and even freedmen, were not admitted into the ranks of the army. In cases of urgent public danger, such as after the defeat of Cannæ, slaves were purchased by the state and sent to the army, and if they behaved well they were emancipated. (Livy, xxii. 57, and xxiv. 14 16.)

They were not, however, denied the rites of burial, and numerous inscriptions attest that monuments were often erected to the memory of deceased slaves by their masters, their fellows, or friends, some of which bear the letters D. M., "Diis Manibus." Slaves were often buried in the family burying-place of their masters. The "sepulchretum" or burial-vault of the slaves and freedmen of Augustus and his wife Livia, discovered in 1726 near the Via Appia, and which has been illustrated by Bianchini and Gori, and another in the same neighbourhood also belonging to the household of the early Cæsars, and containing at least 3000 urns, with numerous inscriptions, which have been illustrated by Fabretti, throw much light upon the condition and domestic habits of Roman slaves in the service of great families.

With regard to the classification and occupations of slaves, the first division was into public and private. Public slaves were those which belonged to the state or to public bodies, such as provinces, municipia, collegia, decuriæ, &c., or to the emperor in his sovereign capacity, and employed in public duties, and not attached to his household or private estate. Public slaves were either derived from the share of captives taken in war which was reserved for the community or state, or were acquired by purchase and other civil process. Public slaves of an inferior description were engaged as rowers on board the fleet, or in the construction and repair of roads and national buildings. Those of a superior description were employed as keepers of public buildings, prisons, and other property of the state, or to attend magistrates, priests, and other public officers, as watchmen, lictors, executioners, watermen, scavengers, &c.

Private slaves were generally distributed into urban and rustic; the former served in the town houses, and the others in the country. Long lists of the different duties performed by slaves of each class are given by Pignorius, 'De Servis et eorum apud Veteres Ministeriis,' Amsterdam, 1674; Popma, 'De Operis Servorum,' ibid, 1672; and Blair, 'An Inquiry into the State of Slavery amongst the Romans,' Edinburgh, 1833, which is a very useful little book. For all the necessities of domestic life, agriculture, and handicraft, and for all the imaginable luxuries of a refined and licentious people, there was a corresponding denomination of slaves. Large sums were occasionally paid for slaves of certain peculiar kinds, some of which we should consider the least useful. Eunuchs were always very dear. A "morio," or fool, was sometimes sold for 20,000 nummi, or about 160*l*. Dwarfs and giants were also in great request. Marcus Antonius paid for a pair of handsome youths 200 sestertia, or 1600*l*. Actors and actresses, and dancers, sold very dear, as well as females of great personal attractions who were likely to bring in great gains to their owners by prostitution. A good cook was valued at four talents, or 772*l*. Medical men, grammarians, amanuenses, anagnostæ, or readers, and short-hand writers, were in considerable request. With regard to ordinary slaves, the price varied from 50*l*. to 20*l*., according to their abilities and other circumstances. After a victorious campaign, when thousands of captives were sold at once on the spot for the purpose of prize-money, to the slave-dealers who followed the armies, the price sank very low. Thus, in the camp of Lucullus in Pontus (Plutarch, 'Lucullus,' c. 14) slaves were sold for four drachmæ, or two shillings and sevenpence, a head; but the same slaves, if brought to the Roman market, would fetch a much higher price. Home-born slaves, distinguished by the name of "vernæ," in contradistinction to "servi empti," or "venales," or imported slaves, were generally treated with greater indulgence by their masters in whose families they had been brought up; and they generally were considered of inferior value to the imported slaves, being considered as spoilt and troublesome. The number of slaves born in Roman families appears at all times to have been far inferior to that of the imported slaves.

There was a brisk trade in slaves carried on from the coasts of Africa, the Euxine, Syria, and Asia Minor. The island of Delos was at one time a great mart for slaves, who were imported thither by the Cilician pirates. (Strabo, p. 668, Casaub.) The Illyrians procured numerous slaves for the Italian market, whom they bought or stole from the barbarous tribes in their neighbourhood. But the chief supply of slaves was derived from Asia and Africa. In most countries it was customary for indigent parents to sell their children to slave-dealers. Criminals were also in certain cases condemned to slavery, like the galley-slaves of our own times.

Both law and custom forbade prisoners taken in civil wars, especially in Italy, to be dealt with as slaves; and this was perhaps one reason of the wholesale massacres of captives by Sulla and the Triumviri. In the war between the party of Otho and Vitellius, Antonius, who commanded the army of the latter, having taken Cremona, ordered that none of the captives should be detained, upon which the soldiers began to kill those who were not privately ransomed by their friends.

In the later period of the empire free-born persons of low condition were glad to secure a subsistence by labour on the estates of the great landowners, to which, after a continued residence for thirty years, they and their families became bound by a tacit agreement under the name of Coloni, Rustici, Adscriptitii, &c. The phrase "servi terræ," which is applied to them, shows their connection with the soil. They could marry, which slaves could not. Though they bear a considerable resemblance to the serfs and villeins (villani) of the middle ages, yet there are some important points of difference, and there is no evidence of any historical connection between the Coloni and Villani. The subject of the Coloni is discussed by Savigny, 'Ueber den Römischen Colonat; Zeitschrift für Geschicht. Rechtswissenschaft,' vol. vi.

The customary allowance of food for a slave appears to have been four Roman bushels, "modii," of corn, mostly "far," per month for country slaves, and one Roman libra or pound daily for those in town. Salt and oil were occasionally allowed, as well as weak wine. Neither meat nor vegetables formed part of their regular allowance; but they got, according to seasons, fruit, such as figs, olives, apples, pears, &c. (Cato, Columella and Varro.) Labourers and artisans in the country were shut up at night in a house ("ergastulum"), in which each slave appears to have had a separate cell. Columella adverts to some distinction between the ergastulum for ordinary labourers and that for ill-behaved slaves, which latter was in fact a prison, often under ground; but generally speaking the ergastula in the later times of the republic and under the empire appear to have been no better than prisons in which freemen were sometimes confined after being kidnapped. The men often worked in chains. The overseers of farms and herdsmen had separate cabins allotted to them. Slaves enjoyed relaxation from toil on certain festivities, such as the Saturnalia.

The number of slaves possessed by the wealthy Romans was enormous. Some individuals are said to have possessed 10,000 slaves. Scaurus possessed above 4000 domestic and as many rustic slaves. In the reign of Augustus, a freedman who had sustained great losses during the civil wars left 4116 slaves, besides other property.

A master had, as a general rule, the power of manumitting his slave, and this he could effect in several forms, by vindicta, census, or by testamentum. The Lex Ælia Sentia, as already mentioned, laid various restrictions on manumission. Among other things it prevented persons under twenty years of age from manumitting a slave except by the vindicta, and with the approbation of the consilium, which at Rome consisted of five senators and five Roman equites of legal age (puberes), and in the provinces consisted of twenty recuperatores, who were Roman citizens. (Gaius, i. 20, 38.) The Lex Ælia Sentia also made all manumissions void which were effected to cheat creditors or defraud patrons of their rights. The Lex Furia Caninia, which was passed about A.D. 7, limited the whole number of slaves who could be manumitted by testament to 100, and when a man had fewer than 500 slaves, it determined by a scale the number that he could manumit. This lex only applied to manumission by testament. (Gaius, i. 42, &c.)

In the earlier ages of the Republic, slaves were not very numerous, and were chiefly employed in household offices or as mechanics in the towns. But after the conquests of Rome spread beyond the limits of Italy the influx of captives was so great, and their price fell so low, that they were looked upon as a cheap and easily renewed commodity, and treated as such. The condition of the Roman slave, generally speaking, became worse in the later ages of the republic; and many of the emperors, even some of the worst of them, interfered on behalf of the slave. Augustus established courts for the trial of slaves who were charged with serious offences, intending thus to supersede arbitrary punishment by the masters, but the law was not made obligatory upon the masters to bring their slaves before the courts, and it was often evaded. By a law passed in the time of Claudius, a master who exposed his sick or infirm slaves forfeited all right over them in the event of their recovery. The Lex Petronia, probably passed in the time of Augustus, or in the reign of Nero, prohibited masters from compelling their slaves to fight with wild beasts, except with the consent of the judicial authorities, and on a sufficient case being made out against the slave. Domitian forbade the mutilation of slaves. Hadrian suppressed the ergastula, or private prisons for the confinement of slaves; he also restrained proprietors from selling their slaves to keepers of gladiators, or to brothel-keepers, except as a punishment, in which case the sanction of a judge (judex) was required. Antoninus Pius adopted an old law of the Athenians by which the judge who should be satisfied of a slave being cruelly treated by his owner, had power to oblige the owner to sell him to some other person. The judge, however, was left entirely to his own discretion in determining what measure of harshness in the owner should be a proper ground for judicial interposition. Septimius Severus forbade the forcible subjection of slaves to prostitution. The Christian emperors went further in protecting the persons of slaves. Constantine placed the wilful murder of a slave on a level with that of a freeman; and Justinian confirmed this law, including within its provisions cases of slaves who died under excessive punishment. Constantine made also two laws, both nearly in the same words, to prevent the forcible separation of the members of servile families by sale or partition of property. One of the laws, dated A.D 334, was retained by Justinian in his code. The church also powerfully interfered for the protection of slaves, by threatening excommunication against owners who put to death their slaves without the consent of the judge; and by affording asylum within sacred precincts to slaves from the anger of unmerciful masters. A law of Theodosius I. authorised a slave who had taken refuge in a church to call for the protection of the judge, that he might proceed unmolested to his tribunal in order that his case might be investigated. After Christianity became the predominant religion in the Roman world, it exercised in various ways a beneficial influence upon the condition of the slaves, without, however, interfering, at least for centuries, with the institution of slavery itself. Even the laws of the Christian emperors which abolished the master's power of life and death over his slave were long evaded. Salvianus ('De Gubernatione Dei,' iv.) informs us that in the provinces of Gaul, in the 5th century, masters still fancied that they had a right to put their slaves to death. Macrobius ('Saturn.', i. 11) makes one of his interlocutors, though a heathen, expatiate with great eloquence on the cruel and unjust treatment of slaves. In Spain, in the early period of the Visigothic kings, the practice of putting slaves to death still existed, for in the 'Foro Judicum' (b. vi., tit. 5) it is said that as some cruel masters in the impetuosity of their pride put to death their slaves without reason, it is enacted that a public and regular trial shall take place previous to their condemnation. Several laws and ecclesiastical canons forbade the sale of Christians as slaves to Jews or Saracens and other unbelievers.

The northern tribes which invaded the Western empire had their own slaves, who were chiefly Slavonian captives, distinct from the slaves of the Romans or conquered inhabitants. In course of time, however, the various classes of slaves merged into one class, that of the "adscripti glebæ," or serfs of the middle ages, and the institution of Roman slavery in its unmitigated form became obliterated. The precise period of this change cannot be fixed; it took place at various times in different countries. Slaves were exported from Britain to the Continent in the Saxon period. Giraldus Cambrensis, William of Malmesbury, and others, accuse the Anglo-Saxons of selling their female servants and even their children to strangers, and especially to the Irish, and the practice continued even after the Norman conquest. In the canons of a council held at London, A.D. 1102, it is said, "Let no one from henceforth presume to carry on that wicked traffic by which men in England have been hitherto sold like brute animals." (Wilkin's 'Concilia,' i. p. 383.)

But although the traffic in slaves ceased among the Christian nations of Europe, it continued to be carried on by the Venetians across the Mediterranean in the age of the Crusades. The Venetians supplied the markets of the Saracens with slaves purchased from the Slavonian tribes which bordered on the Adriatic. Besides, as personal slavery and the traffic in slaves continued in all Mohammedan countries, Christian captives taken by Mussulmans were sold in the markets of Asia and Northern Africa, and have continued to be sold till within our own times, when Christian slavery has been abolished in Barbary, Egypt, and the Ottoman empire, by the interference of the Christian powers, the emancipation of Greece, and the conquest of Algiers by the French.

With the discovery of America, a new description of slavery and slave-trade arose. Christian nations purchased African negroes for the purpose of employing them in the mines and plantations of the New World. The natives of America were too weak and too indolent to undergo the hard work which their Spanish task-masters exacted of them, and they died in great numbers. Las Casas, a Dominican, advocated with a persevering energy before the court of Spain the cause of the American aborigines, and reprobated the system of the "repartimientos," by which they were distributed in lots like cattle among their new masters. But it was necessary for the settlements to be made profitable in order to satisfy the conquerors, and it was suggested that negroes from Africa, a more robust and active race than the American Indians, might be substituted for them. It was stated that an able-bodied negro could do as much work as four Indians. The Portuguese were at that time possessed of a great part of the coast of Africa, where they easily obtained by force or barter a considerable number of slaves. The trade in slaves among the nations of Africa had existed from time immemorial. It had been carried on in ancient times: the Garamantes used to supply the slave-dealers of Carthage, Cyrene, and Egypt with black slaves which they brought from the interior. The demand for slaves by the Portuguese in the Atlantic harbours gave the trade a fresh direction. The petty chiefs of the interior made predatory incursions into each other's territories, and sold their captives, and sometimes their own subjects, to the European traders. The first negroes were imported by the Portuguese from Africa to the West Indies in 1503, and in 1511 Ferdinand the Catholic allowed a larger importation. These, however, were private and partial speculations; it is said that Cardinal Ximenes was opposed to the trade because he considered it unjust. Charles V., however, being pressed on one side by the demand for labour in the American settlements, and on the other by Las Casas and others who pleaded the cause of the Indian natives, granted to one of his Flemish courtiers the exclusive privilege of importing 4000 blacks to the West Indies. The Fleming sold his privilege for 25,000 ducats to some Genoese merchants, who organised a regular slave-trade between Africa and America. As the European settlements in America increased and extended, the demand for slaves also increased; and all European nations who had colonies in America shared in the slave-trade. It is generally understood that the slaves of the Spaniards, especially in Continental America, were the best treated of all. But the negro slaves in general were exactly in the same condition as the Roman slaves of old, being saleable, and punishable at the will of their owners Restrictions, however, were gradually introduced by the laws of the respective states, in order to protect the life of the negro slave against the caprice or brutality of his owner. In the British colonies, especially in the latter part of the last century and the beginning of the present, much was done by the legislature; courts were established to hear the complaints of the slaves, flogging of females was forbidden, the punishment of males was also limited within certain bounds, and the condition of the slave population was greatly ameliorated. Still the advocates of emancipation objected to the principle of slavery as being unjust and unchristian; and they also appealed to experience to show that a human being cannot be safely trusted solely to the mercy of another.

But long before they attempted to emancipate the slaves, the efforts of philanthropists were directed to abolish the slave traffic, which desolated Africa, wholly prevented its advance in civilisation, and encouraged the maltreatment of the negroes in the colonies, by affording an unlimited supply, and making it not the planter's interest to keep up his stock in the natural way. The attention of mankind was first effectually awakened to the horrors of this trade by Thomas Clarkson. His labours, with the aid of the zealous men, chiefly Quakers, who early joined him, prepared the way for Mr. Wilberforce, who brought the subject before parliament in 1788, and although, after his notice, the motion, owing to his accidental illness, was first brought forward by Mr. Pitt, Mr. Wilberforce was throughout the great parliamentary leader in the cause, powerfully supported in the country by Thomas Clarkson and others, as Richard Phillips, George Harrison, William Allen, all of the Society of Friends, Mr. Stephen, who had been in the West Indies as a barrister, and Mr. Z. Macaulay, who had been governor of Sierra Leone, and had also resided in Jamaica. A bill was first carried (brought in by Sir W. Dolben) to regulate the trade until it could be abolished, and this in some degree diminished the horrors of the middle passage. But the question of abolition was repeatedly defeated, until 1804, when Mr. Wilberforce first carried the bill through the Commons; it was thrown out in the Lords, and next year it was again lost even in the Commons. Meanwhile the capture of the foreign colonies, especially the Dutch, during the war, frightfully increased the amount of the trade, by opening these settlements to British capital; and at one time the whole importation of slaves by British vessels amounted to nearly 60,000 yearly, of which about a third was for the supply of our old colonies. At length, in 1805, an order in council prohibited the slave-trade in the conquered colonies. Next year the administration of Lord Grenville and Mr. Fox carried a bill through, prohibiting British subjects from engaging in the trade for supplying either foreign settlements or the conquered colonies. A resolution moved by Mr. Fox, the last time he took any part in public debate, was also carried in 1806, pledging the Commons to a total abolition of the trade early next session, and this was, on Lord Grenville's motion, adopted by the Lords. Accordingly next year the General Abolition Bill was brought in by Lord Howick (afterwards Earl Grey), and being passed by both houses, received the royal assent on the 25th of March, 1807. This act prohibited slave-trading from and after the 1st of January, 1808; but as it only subjected offenders to pecuniary penalties, it was found that something more was required to put down a traffic the gains of which were so great as to cover all losses by capture. In 1810 the House of Commons, on the motion of Mr. Brougham, passed unanimously a resolution, pledging itself early next session effectually to prevent "such daring violations of the law;" and he next year carried a bill making slave-trading felony, punishable by fourteen years' transportation, or imprisonment with hard labour. In 1824 the laws relating to the slave-trade were consolidated, and it was further declared to be piracy, and punishable capitally, if committed within the Admiralty jurisdiction. In 1837 this was changed to transportation for life, by the acts diminishing the number of capital punishments. Since the Felony Act of 1811, the British colonies have entirely ceased to have any concern in this traffic. If any British subjects have engaged in it, or any British capital has been embarked in it, the offence has been committed in the foreign trade.

The Duke of Wellington, while ambassador at Paris in 1814, used every effort to obtain from the restored Bourbon government a prohibition of the traffic in slaves; but the French West Indian interest and commercial jealousy of England frustrated all his attempts. The first French law abolishing the slave-trade was a decree issued by Napoleon on the 29th of March, 1815, during the Hundred Days, after his return from Elba. It prohibited any vessel from fitting out for the trade, either in the ports of France or in those of her colonies; and the introduction or sale in the French colonies of any negro obtained by the trade, whether carried on by French subjects or foreigners. The influence of Great Britain was again strenuously exerted at the peace in 1815, to obtain the concurrence of foreign powers in the abolition; and the object has been steadily kept in view by this country, and every opportunity of forwarding it taken advantage of, down to the present time. The consequence has been that now nearly all the powers in Europe and America have passed laws, or entered into treaties, prohibiting the traffic.

To the General Treaty signed by the representatives of Austria, France, Great Britain, Portugal, Prussia, Russia, Spain, and Sweden, assembled in Congress at Vienna, on the 9th of June, 1815, was annexed, as having the same force as if textually inserted, a Declaration, signed at the same place by the Plenipotentiaries of certain of the powers, on the 8th of February preceding, to the following effect:—that seeing several European governments had already, virtually, come to the resolution of putting a stop to the slave trade, and that, successively, all the powers possessing colonies in different parts of the world had acknowledged, either by legislative acts, or by treaties or other formal engagements, the duty and necessity of abolishing it; and that by a separate article of the late treaty of Paris (30th May, 1814), Great Britain and France had engaged to unite their efforts at this Congress of Vienna to induce all the powers of Christendom to proclaim its universal and definitive abolition; the members of the Congress now declared, in the face of Europe, that they were animated with the sincere desire of concurring in the most prompt and effectual execution of this measure by all the means at their disposal. And this Declaration was renewed by the plenipotentiaries of Austria, France, Great Britain, Prussia, and Russia, assembled in Congress at Verona, in resolutions adopted in a conference held on the 28th of November, 1822; in which, however, it is admitted that, "notwithstanding this declaration, and in spite of the legislative measures which have in consequence been adopted in various countries, and of the several treaties concluded since that period between the maritime powers, this commerce, solemnly proscribed, has continued to this very day; that it has gained in activity what it may have lost in extent; that it has even taken a still more odious character, and more dreadful from the nature of the means to which those who carry it on are compelled to have recourse."

The following will be found, we believe, to be a correct and complete list of the treaties and conventions for the suppression of the slave-trade that have been made by this country with other states since the general peace:—

In 1814, with France, by Additional Articles to the Definitive Treaty of Peace signed at Paris 30th May (engaging that the slave-trade should be abolished by the French government in the course of five years); and with the Netherlands, by treaty of London, 13th August. Its abolition had also been stipulated in the Treaty of Kiel, concluded with Denmark on the 14th of January.

In 1815, with France, by Additional Article to Definitive Treaty signed at Paris 20th November (by which the two powers, having each already, in their respective dominions, prohibited, without restriction, their colonies and subjects from taking any part whatever in the slave-trade, engage to renew their efforts, through their ministers at the courts of London and Paris, for its entire and definitive abolition); and with Portugal, by Treaty signed at Vienna 22nd January (referring to Treaty of Alliance concluded at Rio de Janeiro 19th February, 1810, in which the Prince Regent of Portugal had declared his determination to adopt the most efficacious means for bringing about a gradual abolition of the slave-trade; and making it now unlawful for any of the subjects of the crown of Portugal to purchase slaves, or to carry on the slave-trade, on any part of the coast of Africa to the northward of the equator).

In 1817, with Portugal, by Convention signed at London 28th July (prohibiting universally the carrying on of the slave-trade by Portuguese vessels bound for any port not in the dominions of his Most Faithful Majesty; and restricting it in other circumstances); with Portugal, by Separate Article, signed at London 11th September (referring to arrangements to be adopted "as soon as the total abolition of the slave-trade, for the subjects of the crown of Portugal, shall have taken place"); with Spain, by Treaty signed at Madrid 23rd September (by which his Catholic Majesty engages that the slave-trade shall be abolished throughout the entire dominions of Spain on the 30th of May, 1820, and that in the mean time it shall not be lawful for any of the subjects of the crown of Spain to purchase slaves, or to carry on the slave-trade, on any part of the coast of Africa to the north of the equator, or in vessels bound for any port not in the dominions of his Catholic Majesty; and by which the restrictions under which the trade may be carried on in other circumstances are specified); and with Radama, king of Madagascar and its dependencies, by Treaty signed at Tamatave 23rd October.

In 1818, with the Netherlands, by Treaty signed at the Hague 4th May (specifying restrictions under which the reciprocal right of visitation and search is to be exercised).

In 1820, with Madagascar, by Additional Articles signed at Tananarivoux 11th October.

In 1822, with the Imaum of Muscat, by Treaty signed at Muscat 10th September; with Netherlands, by Explanatory and Additional Articles, signed at Brussels 31st December; and with Spain, by Explanatory Article signed at Madrid 10th December.

In 1823, with Netherlands, by Additional Article signed at Brussels 25th January; with Portugal, by Additional Articles signed at Lisbon 15th March; and with Madagascar, by Additional Articles signed at Tamatave 31st May.

In 1824, with Sweden, by Treaty of Stockholm, 6th November (arranging reciprocal right of visitation by the ships of war of the two countries).

In 1826, with Brazil, by Treaty of Rio de Janeiro, 23rd November (renewing, on the separation of that empire from Portugal, the stipulations of the treaties subsisting with the latter power).

In 1831, with France, by Convention of Paris, 30th November (stipulating mutual right of search, within certain seas, by a number of ships of war to be fixed every year for each nation by special agreement).

In 1833, with France, by Supplementary Convention of Paris, 22nd March (further regulating the right of visitation by duly authorised cruisers).

In 1834, with Denmark, by Treaty of Copenhagen, 26th July (containing the accession of his Danish Majesty to the Conventions between Great Britain and France of 1831 and 1833); with Sardinia, by Treaty of Turin, 8th August (containing accession of that power to same conventions); and with Sardinia, by Additional Article, signed at Turin, 8th December (respecting place of landing of negroes found in vessels with Sardinian flag).

In 1835, with Spain, by Treaty of Madrid, 28th June (abolishing slave-trade on part of Spain henceforward, totally and finally, in all parts of the world; and regulating a reciprocal right of search); and with Sweden, by Additional Article to Treaty of 1824, signed at Stockholm 15th June.

In 1837, with Tuscany, by Convention signed at Florence 24th November (containing accession of the Grand Duke of Tuscany to French Conventions of 1831 and 1833); with Hanse Towns, by Convention signed at Hamburg 9th June (to same effect); and with Netherlands, by Additional Article to Treaty of 1818, signed at the Hague 7th February.

In 1838, with the Kingdom of the Two Sicilies, by Convention signed at Naples 14th February (containing accession of his Sicilian Majesty to French Conventions of 1831 and 1833).

In 1839, with Republic of Venezuela, by Treaty signed at Caracas 15th March (abolishing for ever the traffic in slaves, so far as it consists in the conveyance of negroes from Africa; expressing the determination of Venezuela to preserve in force the provisions of a law passed in February, 1825, declaring Venezuelans found engaged in that trade to be pirates and punishable with death, and regulating a mutual right of visitation); with Chile, by Treaty signed at Santiago 19th January; with Uruguay, by Treaty signed at Montevideo 13th July; with Argentine Confederation, by Treaty signed at Buenos Ayres 24th May; and with Hayti, by Convention signed at Port-au-Prince 23rd December.

In 1840, with Bolivia, by Treaty signed at Sucre 25th September; and with Texas, by Treaty signed at London 16th November.

In 1841, with France, by Treaty signed at Paris 20th December, which however the French government afterwards refused to ratify; with Mexico, by Treaty signed at Mexico 24th February; and with Austria, Prussia, and Russia, by Treaty signed at London 20th December.

In 1842, with the United States of North America, by Treaty signed at Washington 9th August (stipulating that each party shall maintain on the coast of Africa a naval force, carrying in all not less than eighty guns, "to enforce, separately and respectively, the laws, rights, and obligations of each of the two countries for the suppression of the slave-trade; the said squadrons to be independent of each other," but "to act in concert and co-operation, upon mutual consultation, as exigencies may arise"); with the Argentine Republic; and with the Republic of Hayti.

In 1842, the Ashburton Treaty with the United States of America, by which it was stipulated that each party was to maintain a separate squadron on the coast of Africa to suppress the slave-trade, but if the vessel seized on suspicion was under American colours she was to be delivered to an American cruiser, and if under any other to be given up to the British, to be decided upon as to the fact of slave trading being established, by the courts of the respective countries. [SEARCH, RIGHT OF.] This divided action has not been found effective. With Portugal, by Treaty signed at Lisbon 3rd July.

In 1845, with Brazil; and with France, by a Convention signed at London on the 29th of May (by which each power is to keep up an equal naval force on the western coast of Africa, and the right of visitation is to be exercised only by cruisers of the nation whose flag is carried by the suspected vessel).

The History of the Abolition is to be found in the work under that title by T. Clarkson, and the state of the law, as well as the treatment of slaves practically in the colonies, is most fully treated of in a work on that subject by Mr. Stephen. The writings of the late Sir John Jeremie also contain much useful information on the condition of slavery in the British colonies just before the Emancipation Act. T. Clarkson's other works on the nature of the traffic, which first exposed it to the people of this country, were published in 1787.

The slave-trade was suppressed, but slavery continued to exist in the British colonies. In 1834 the British parliament passed an act by which slavery was abolished in all British colonies, and twenty millions sterling were voted as compensation money to the owners. This act (3 & 4 Wm. IV. c. 73) stands prominent in the history of our age. No other nation has imitated the example. The emancipated negroes in the British colonies were put on the footing of apprenticed labourers. By a subsequent act (1 Vic. c. 19) all apprenticeships were to cease after the 1st of August, 1840, but the day was anticipated in all the West Indian colonies by acts of the colonial legislatures. Slavery exists in the Spanish and Portuguese colonies, and in the southern states of the North American Union. The new republics of Spanish America, generally speaking, emancipated their slaves at the time of the revolution. As the slave population in general does not maintain its numbers by natural increase, and as plantations in America are extended, there is a demand for a fresh annual importation of slaves from Africa, which are taken to Cuba, Puerto Rico, and Monte Video. Since the slave-trade has been declared to be illegal, the sufferings of the slaves on their passage across the Atlantic have been greatly increased, owing to its being necessary for masters of slave-traders to conceal their cargoes by cooping up the negroes in a small compass, and to avoid the British cruisers; they are often thrown overboard in a chase. There is a considerable loss of life incident to the seizing of slaves by force in the hunting excursions after negroes, and in the wars between the chieftains of the interior for the purpose of making captives. There is a loss on their march to the sea-coast; the loss in the middle passage is reckoned on an average at one-fourth of the cargo; and, besides this, there is a further loss, after landing, in what is called the "seasoning" of the slaves. The Portuguese flag has been openly used, with the connivance of the authorities, for carrying on the slave-trade. The Spanish flag has also been used, though with caution, owing to the treaty between England and Spain which formally abolishes the slave-trade on the part of Spain. A mixed commission court of Spaniards and British exists at Havana to try slavers; but pretexts are never wanting to elude the provisions of the treaty. There seems indeed to be a great difficulty in obtaining the sincere co-operation of all Christian powers to put down the slave-trade effectually, although it is certain that in all but the Portuguese and Spanish settlements the traffic has now almost entirely ceased.

Besides the slave-trade on the Atlantic, there is another periodical exportation of slaves by caravans from Soudan to the Barbary states and Egypt, the annual number of which is variously estimated at between twenty and thirty thousand. There is also a trade carried on by the subjects of the Imaum of Muscat, who export slaves in Arab vessels from Zanzibar and other ports of the eastern coast of Africa, to Arabia, Persia, India, Java, and other places. The Portuguese also export slaves from their settlements on the Mozambique coast, to Goa, Diu, and their other Indian possessions.

By a law of the Koran, which, however, is not always observed in all Mohammedan countries, no Mussulman is allowed to enslave one of his own faith. The Moslem negro kingdoms of Soudan supply the slave-trade at the expense of their pagan subjects or neighbours, whom they sell to the Moorish traders. Mohammedan powers will probably never suppress this trade of their own accord.

There is a considerable internal slave-trade in the United States of North America. Negroes are bred and sold in Maryland and Virginia, and some other of the slave-holding states, and carried to the more fertile lands of Alabama, Louisiana, and other southern states. But the attempts of the south, for some time successful, to legalise the recapturing of their escaped slaves in the non-slaveholding states, has at length led to a reaction. On the other hand the election of a president opposed to the views of the slave states, has served as a pretext for the southern states to secede from the Union, and form a new confederacy based on the fullest recognition of slavery as an institution. The issue is however still pending, it being as yet uncertain whether either party will make concessions, or whether or not coercive measures will be employed.

It is maintained by some that the African slave-trade cannot be effectually put down by force, and that the only chance of its ultimate suppression is by civilising central Africa, by encouraging agricultural industry and legitimate branches of commerce, and at the same time spreading education and Christianity; and also by giving the protection of the British flag to those negroes who would avail themselves of it. It is certain that if other countries will not exert themselves, the abolition must be postponed to this remote period. The Africans sell men because they have no other means of procuring European commodities, and there seems no doubt that one result of the slave-trade is to keep central Africa in a state of barbarism. Great hopes are entertained, and a prospect has been afforded, that the influence of commerce will tend to lessen the hateful trade. From the western coast of Africa a large amount of palm-oil is now exported, and as the cultivation of the plant, and the production of the oil, will render the profit of the labour more productive to the rulers than the sale of the labourer, it may induce them to discontinue the practice of undertaking wars for the purpose of procuring captives for sale. It is also hoped by many that cotton may be successfully raised in Africa.

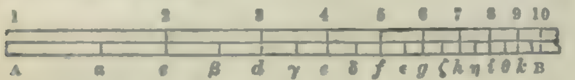
The amount of the slave population now existing in America is not easily ascertained. In Brazil it is estimated there are 2,000,000 negroes, of whom three-fourths are slaves. The slaves in Cuba, according to the census of 1840, numbered 425,521. In the United States the number of slaves was 3,204,313 by the census of 1850, which is 716,989 more than the number according to the census of 1840; yet ten states which returned slaves in 1840 returned none in 1850, the holding of them having wholly (or virtually) ceased.

Societies for the ultimate and universal abolition of slavery exist in England, France, and the United States, and they publish their reports; and a congress was held in London, in June, 1840, of delegates from many countries to confer upon the means of effecting it. The American Society has formed a colony called Liberia, near Cape Mesurado, on the west coast of Africa, where negroes who have obtained their freedom in the United States are sent, if they are willing to go [LIBERIA, in GEOG. DIV.] The English government has a colony for a similar purpose at Sierra Leone, where negroes who have been seized on board slavers by English cruisers are settled. [SIERRA LEONE, in GEOG. DIV.] Several thousands of negroes who have escaped from slavery in the United States are now settled in Canada, earning a livelihood by their own industry.

SLEEP; SLEEP-WALKING. [SOMNAMBULISM.]

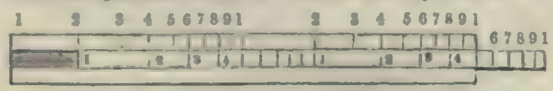
SLIDE (or SLIDING) RULE. The sliding-rule is an instrument for the mechanical performance of addition and subtraction, which is converted into an instrument for the mechanical performance of multiplication and division by the use of logarithmic scales, instead of scales of equal parts.

This instrument has been greatly undervalued in our country, in which it was invented, and is very little known on the Continent; for though a French work on the subject, published in 1825, which is followed by the writer of a more recent mathematical dictionary in the same language, assures us that in England the sliding rule is taught at schools at the same time with the letters of the alphabet, we believe it would be more correct to say that nine Englishmen out of ten would not know what the instrument was for if they saw it, and that of those who even know what it is for, not one in a hundred would be able to work a simple question by means of it. For a few shillings most persons might put into their pockets some hundred times as much power of calculation as they have in their heads: and the use of the instrument is attainable without any knowledge of the properties of logarithms, on which its principle depends.

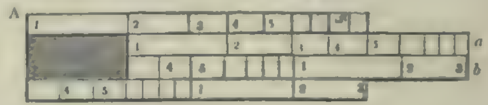


We have before us a logarithmic scale, of which A B, called the *radius*, may stand for the logarithm of 10, 100, 1000, &c.: but if A B should be, say the logarithm of 100, then A *c* is that of 20, A *d* of 30, and so on. If this scale be repeated several times, beginning again at B, and if it be also large enough to be subdivided to a greater extent than can be shown in the diagram, any multiplication can be approximately performed by addition, and any division by subtraction; which may be done with a pair of compasses. That is to say, the figures of the product may be found, exactly or approximately, and the meaning of the figures must be settled from the known character of the result. For example, to find 4 times 15:—First, let A B mean the logarithm of 100, then A *a* is that of 15; next let A B mean the logarithm of 10, then A *e* is that of 4. Take A *a* on the compasses, and set it on to the right of *e*; it will be found that the point *g* is attained, directly under 6. But 4 times 15 must be tens; therefore 60 is meant, or 4 × 15 = 60. Next to divide 90 by 45: from A *k* take A δ, or set off A δ from *k* towards the left. The point *c* will be attained, under 2, which is the quotient. Next to find 7 times 5: set off A *f* from *h* towards the right, and the point γ of the scale following B will be attained, and 35 is the answer. But had it been to multiply 7 by ·5 or 5-tenths, this 35 would have meant 3·5 or 3½. Attempts are made in works professing to explain the sliding-rule to give rules for the determination of the character of the figures in the answer, but without any success. It is all very well for a few chosen examples, but an attempt to do without the book soon shows the insufficiency of rules. If, on a large scale, 653 should be the figures of an answer, common sense, applied to the problem, must say whether it is ·0653, ·653, 6·53, 65·3, 653, 6530, 65300, &c. which is meant. A knowledge of decimal fractions is therefore indispensable.

Now these additions and subtractions might be performed by a pair of rulers made to slide each along the other; but whether they are kept together by the hand, or whether the one ruler slides in a groove along the edge of the other, matters nothing to the explanation. The following diagram represents the two rulers in one relative position. Here 1 on the slide is made to match 2 on the fixed ruler, and the instrument is now in a position to multiply by 2, to perform every division in which the quotient is 2, and to work every question in the rule of three in which the ratio of the first term to either the second or third is that of 2 to 1, or of 1 to 2. And here let us observe, that much the best way of beginning to use the sliding-rule is not by working given questions, but by setting the slide at hazard, and learning to read the questions which are thus fortuitously worked.

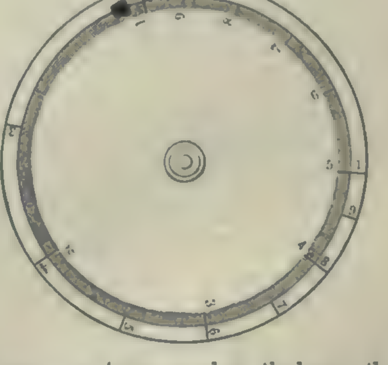


In the cut before us we have the 1 of the slide placed at 2 of the fixed ruler; consequently 6 on the slide comes under what would be 12 of the fixed ruler if the secondary graduations were inserted. Again, 4 comes over 2, and 9 over 45, giving 4 : 2 :: 9 : 4·5, the decimal point being inserted by intuition. To show the sort of results which we obtain from such a slide of 5½-inches radius (or from 1 to 1), we take one of this sort, and throw 1 of the slide at hazard between 225 and 230 on the fixed ruler, a little farther to the right than it is on the preceding diagram; guessing at the interval, it seems 228·5. We detect it more exactly by looking at 5 on the slide, which is hardly visible in advance of 114 on the scale. As far then as the divisions, aided by our judgment of this interval, inform us, we have 114÷5 = 22·85, the truth being 22·8. Again, we find 628 (fixed) just over 275 (slide), the 8 being estimated; hence, by the scales we learn that 628÷275 = 2·285; the truth being 2·2836. Thirdly, we estimate that 1725 (fixed) falls over 757 (slide), and that 276 (fixed) falls over 121 (slide). That is, the ruler informs us that 1725 : 757 :: 276 : 121; the fourth term should be 121·12, as found by computation. We take a larger scale, having 7½ inches of radius, and setting 1 on the slide to 228·5, we find 1725 appears to fall over what we should judge to be 756 rather than 757. Now 1725÷757 = 2·2787, and 1725÷756 = 2·2818. Both give on the scales 2·285, so that the advantage is slightly in favour of the larger scale, but not so much as we should have expected. We now try one of 24 inches radius, and setting 1 on the slide to 2·285 on the fixed ruler, we find that 1725 (fixed) falls over 754·7 (slide), the last 7 being estimation. Now 1725÷754·7 = 2·2857, which gives the advantage again (but not so decidedly as might have been expected) to the large rule. The fact is, that it is rather ease than proportionate accuracy which is gained by the large rules: the preceding results required care and close attention on the 5½ inch rule; were obtained with moderate care on the 7½-inch; and taken off instantly from the 24-inch rule. Moreover, divisions on wood, made in the usual way, do not allow accuracy to increase with the size: if these rulers were divided on brass, and with the precautions taken in astronomical instruments, it would be a very different thing; but after all, the wonder is that the common wooden rules should be so accurate as they are.



The next step in the description is as follows:—It matters nothing whether the second scale be really made consecutive with the first, or occupy any other part of space: provided that when 1 and 1 are brought together on the first scale, 1 and 1 also come together on the second, and that the first slide and its continuations slide equally. We see this in the diagram before us: *a b* is one slide, and A B are two rulers on opposite sides of the groove. When *a b* is pushed home, A and *a* present coinciding scales, as do B and *b*: we should rather say, that the last is not one scale, but the end of one and the beginning of another; the 1 of B and *b* being in the middle. The consequence is, that so long as 1 of the scale *b* is not pushed out so far as to fall out of the groove (which is never necessary, since there is a whole scale on B), there is always the power of reading every result of the multiplication in hand. In the diagram, 1 on *b* is pushed out to 2 on B, and on the upper scales (A and *a*) we see 2 × 2 = 4, 2 × 3 = 6, 2 × 4 = 8, 2 × 5 = 10; on the lower (B and *b*), 2 × 4 = 8, 2 × 5 = 10, 2 × 6 = 12, 2 × 7 = 14, 2 × 8 = 16, 2 × 9 = 18, 2 × 10 = 20. This modification was invented by Mr. Silvanus Bevan (Nicholson's 'Journal,' vol. xlix., p. 187); but thirty years before this Mr. Nicholson ('Phil. Trans.', 1787, p. 246) had pointed out how to divide the whole radius into four parts, two on each face.

A simple plan, and in some respects the best, is to make a revolving circle turn upon a fixed one, in which case the scale is its own continuation, as in the following diagram. The two circles have a common pivot, and the upper one turns round on the lower; the rim of the inner circle being bevelled down to the plane of the lower. A complete logarithmic scale is marked on each circumference, and it will readily be seen that the scales are placed so as to point out multiplications by 2, as in the former instances, and also that the recommencement of the scale begins its continuation. Instead of two circles there might be two thin cylinders, turning on a common axis, the graduations being made on the rim. Thirty years ago, an instrument-maker at Paris laid down logarithmic scales on the rims of the box and lid of a common circular snuff-box: one of two inches diameter would be as good an aid to calculation as the common engineer's rule. But either calculators disliked snuff, or snuff-takers calculation, for the scheme was not found to answer, and the apparatus was broken up.



The form first proposed by Oughtred (presently to be mentioned) was a modification of the preceding. Instead of two circles, two pointing radii were attached to the centre of one circle, on which a number of concentric circles were drawn, each charged with a logarithmic scale. These pointers would either move round together, united by friction, or open and shut by the application of pressure: they were in fact a pair of compasses, laid flat on the circle, with their pivot at its centre. Calling these pointers antecedent and consequent, to multiply A and B the consequent arm must be brought to point to 1, and the antecedent arm then made to point to A. If the pointers be then moved together until the consequent arm points to B, the antecedent arm will point to the product of A and B.

It will be observed that in every construction the logarithmic spaces are very unequal, those near the end of the scale being small when compared with those at the beginning. This is not so great a disadvantage as might be supposed, for it makes the liability to error increase in nearly the same proportion with the result, so that the *per centage* of error in the sliding-rule is nearly the same thing in all its parts. For example, the scale going from 10 to 100, the interval from 10 to 11 is to that from 99 to 100 as 207 to 22, nearly in the proportion of 10 to 1. The tendency to absolute error will be inversely as these intervals, or nearly in the proportion of 1 to 10: the tendency to error is therefore about 10 times as great precisely when the result estimated becomes ten times as great. Oughtred appropriated two circles to his logarithms of sines, and it would be easy in his construction of the 'circles of proportion,' as he called them, to distribute the scale among different circles in such a manner that the graduations should be nearly equal throughout. But the mathematician will easily see that that the most perfect mode of developing this idea would be to lay down the scale on a revolution of a logarithmic spiral, having the pointers joined at its pole. The graduations would then be absolutely at equal distances from each other on the arc of the spiral.

Another modification of the principle of the sliding-rule is as follows:—Let the divisions be all made equal, and the numbers written upon the divisions in geometrical proportion. If this were done to a sufficient extent, any number might be found exactly or nearly enough upon the scale; the only difficulty being that very small divisions do not give room enough to write the numbers. This modification of the principle has been applied in two very useful modes by Mr. MacFarlane. In the first, two cylinders moving on the same axis, on one side and the other of a third, give the means of instantaneously proposing and solving any one out of several millions of arithmetical questions for the use of schools and teachers. In the second, one circle revolving upon another gives the interest upon any sum, for any number of days, at any rate of interest under 10 per cent.

The rules for using the sliding-rule, in its most simple form, may be symbolically expressed in the following manner:—

$$\begin{array}{cc|cc|cc|} 1 & B & A & B & A & C \\ A & AB & 1 & B \div A & B & C \times B \div A \end{array}$$

Thus, if 1 on either ruler be brought opposite to A on the other, B on the first ruler is brought opposite to A B on the other. But if the slide be taken out and inverted, we have the following rules:—

$$\begin{array}{cc|cc|cc|} 1 & B & A & B & A & C \\ A & A \div B & 1 & A \div B & B & A \times B \div C \end{array}$$

We now proceed to some of the additions which are frequently made to sliding-rules, premising that we do not describe any one in particular, but refer for detail to the tracts which are afterwards cited. For the extraction of square or cube roots, or the formation of squares or cubes, the following method is adopted:—In the case of squares and square roots, for instance, there is a pair of scales, one on the slide and one on the fixed ruler, of different radii, the radius of one being twice as long as that on the other: for cubes and cube roots the radius of one is three times as long as the other. On the former scale (that of squares and square roots) the rules are now as follows:—

$$\begin{array}{lccc|ccc|} \text{Longer Rad.} & 1 & A & \sqrt{A} & 1 & B & (\sqrt{B}):A \\ \text{Shorter Rad.} & 1 & AA & A & A & AB^2 & B \\ & A & B & A\sqrt{B} & A & C & A\sqrt{(C:B)} \\ & 1 & B^2\cdot A^2 & B & B & BC^2:A^2 & C \end{array}$$

The denomination of the answer, or the place of the decimal point, must be determined by independent consideration, as before; but there is one circumstance to be attended to in every case in which two of the data are to be read on the shorter scale. For example,* suppose it is required to estimate $\sqrt{(2:7)}$. By the second formula, 7 on the shorter scale is placed opposite to 1 on the longer, and 2 on the shorter scale is then opposite to 1693 on the longer. The answer from the scale is then ·1693, to all appearance; but this is not $\sqrt{(2:7)}$, but $\sqrt{(2:70)}$. The place on the longer scale which should give the answer has no slide opposite to it, but only empty groove. But mark where 1 on the shorter scale is opposite to a part of the longer (between 119 and 120), and push the slide in from left to right till the first 1 on the shorter scale comes where the second now is; then look under the second 2 of the shorter scale, we have 534; and ·534 is the true answer so far as the scale will give it. We have taken the most straightforward plan of reading the rule, and have not space for all the details which are in works on the subject, particularly the method of using the slide of numbers with a scale of numbers above and of square roots below. The following is the general principle applicable to the preceding case:—

It is well known that, whereas in common division the place of the decimal point has nothing to do with the significant figures of the quotient, yet in extracting the square, cube, &c., roots, the figures of the root are altered by a change of the decimal point, unless it be changed by an even number of places in extracting the square root, by three or a multiple of three places in the cube root, and so on. In extracting the square root, a number may either have two figures in its first period, or one; thus ·07616 and ·7616 must (in the rule for extraction) be pointed

$${\cdot}0\dot{7}6\dot{1}6\dot{0} \quad \text{and} \quad {\cdot}7\dot{6}1\dot{6}.$$

Let us call numbers *unidigital* or *bidigital*, according as there are one or two significant figures in the first period. Then the application to the sliding-rule is, that on the shorter scale numbers of the same name must be read either on the same radius or with a whole radius intervening, while numbers of different names must be read on different radii. In the scale for the extraction of the cube root, numbers must be distinguished into unidigital, bidigital, and tridigital; and signifying these by their initial letters, and taking the succession U B T U B T, &c., there must be the same relation between the scales on which they are read that there is between the places of their letters in the preceding list. Thus, if U be read on one radius, T must either be read on that immediately preceding, or on the next but one. Thus, in the preceding question, which we first solved wrongly, we have 2 and 7 to consider on the shorter scale, the pointing of which is—

$$\dot{2}{\cdot}0\dot{0}0\dot{0} \quad \text{and} \quad \dot{7}{\cdot}0\dot{0}0\dot{0},$$

and both are unidigital numbers. Bringing 7 on the shorter scale to 1 on the longer, we see that the next 2 is on a different radius; it would do then for 70, or ·7, or ·007, but not for 7. By the process we followed we took not indeed a 2 on the same radius with our 7, but on the next radius but one, and thus obtained the correct answer. These points, and others (such as the meanings of the lines of sines, tangents, &c., annuities, &c., which are found on several rules) can only be mastered by those who are acquainted theoretically with logarithms, trigonometry, &c.; for after all the sliding-rule will not teach the method of working any question, but will only afford aid in computation—in common multiplication and division, to any one; in higher rules, to those who understand their principles. Oughtred, the inventor, kept the instrument by him many years, out of a settled contempt for those who would apply it without knowledge, having "onely the superficiall scumme and froth of instrumentall trickes and practises;" and wishing to encourage "the way of rationall scientiallists, not of ground-creeping Methodicks." A little distinction between that portion of its use which is generally attainable, and that which requires mathematical knowledge, would have been more reasonable.

On the carpenter's and engineer's sliding-rule are engraved a number of numerals in columns with headings, of which the following is a specimen:—

	SQUARE.			CYLINDER.		GLOBE.	
	FFF	FII	III	FI	II	F	I
CAST IRON	·0022	·323	3·878	·411	4·935	·0043	7·406

These divisors (called gauge-points) are intended to convert into pounds the weight of a rectangular prism, cylinder, or globe, of cast-iron; the first, on three suppositions, namely, all dimensions in feet, one in feet and two in inches, and all in inches; the second, on the suppositions that the length is in feet and the diameter in inches, and that both are in inches; the third, on the supposition that the diameter is either in feet or in inches. We shall here content ourselves with verifying one of these, say the first of those marked "cylinder," which will show the nature of the divisor.

The specific gravity of cast-iron is 7·207, and the content of a cylinder of D *inches* diameter and L *feet* of length is $·7854 \times D^2 L$ divided by 144, in cubic feet. A cubic foot of water weighs 62·321 pounds avoirdupois: one of cast-iron, therefore, weighs $62·321 \times 7·207$; whence the weight of the cylinder is, in pounds,

$$62{\cdot}321 \times 7{\cdot}207 \times {\cdot}7854\, D^2L \div 144, \text{ or } \frac{D^2L}{G};$$

$$\text{where } G = \frac{144}{62{\cdot}321 \times 7{\cdot}207 \times {\cdot}7854}, \text{ or } {\cdot}4082;$$

near enough to ·411 to illustrate our object, but showing that the computer of this divisor used a specific gravity slightly differing from the above. The rule in all the cases is to multiply the three dimensions together, diameters or lengths, and to divide by the divisor given in the table. The term gauge-point, which properly belongs to the part of the scale on which the divisor is marked, has passed to the divisor itself.

---

* The reader will not understand this, unless with the scale in his hand. The common carpenter's rule or Bevan's rule will do, in which two consecutive radii are on the shorter scale, and one radius of twice the length on the longer.

The following list of sliding-rules contains all, or nearly all, which can be useful to any one :—

1. Common Engineer's Rule, or Carpenter's Rule in its best form. A double 12-inch rule, a slide of two radii with the same scale on one side, and a scale of one radius of double length on the other, with divisors. (Sold by all rule makers.) There is a description in Kentish's 'Treatise on a Box of Instruments,' &c., London, 1839.

2. Bevan's Engineer's Rule, 12 inches. Has slides on both faces (which may be exchanged), and serves for squares, cubes, square roots of cubes, &c. There are scales on the backs of the slides and in the grooves, for sines, tangents, inverted numbers, compound interest and annuities at 5 per cent. (Cary, Strand, with an explanatory treatise.)

3. Henderson's Double-Slide Rule, 12 inches. Has two parallel contiguous slides, with scales of numbers fixed above and below, and solves at one operation most sets of multiplications and divisions not exceeding five operations. At the back are tables of divisors for solids.

4. Woollgar's Pocket Calculator, 8 inches. The two slides work in either of the grooves : the backs and the grooves have scales of sines, tangents, areas of polygons, circular segments ; interest, annuities, certain and for lives, at several rates of interest. An addition may be made by a metal slip, giving the solution of the same questions as the last rule.

5. Woollgar's Pocket-Book Rule, 6 and 8 inches. Two radii, one under the other, as described in the preceding part [*] of the article ; a line for sines and duplicate proportions at the back of the slide. At the bottom of the groove are sometimes inserted lines for finding the relations of right-angled triangles, for cask-gauging, and for cuttings and embankments.

6. Excise Officer's Sliding Rule, modern form. Sold at the Excise Store-office, and by some of the instrument-makers. The old Excise rule was a thick block, with a slide on each face.

7. Bayley's Rule, (Elliot, Strand) has a scale of numbers, squares, and cubes, and a scale of equal parts, of the length of the line of squares, from which the logarithm of a number can be approximately read. This line is of considerable use in operations connected with higher powers : it is found also in Bevan's rules. The constructor of this scale, which is well divided and convenient, has a full treatise on the whole subject in the press.

Among separate treatises not yet noted are Flower's, 8vo., London, 1768 ; Mackay's, 8vo., 2nd edit., London, 1811 ; do. Leith, 1812 ; 'Instruction sur la Manière de se servir de la Regle à Calcul.,' petit-in-8vo., Paris et Dijon, 1825 ; 'The Universal Ready-Reckoner,' by an Idle Gentleman, 12mo., London, 1839 ; and there is a good deal on the subject in Ingram's 'Concise System of Mathematics,' 12mo., Edinburgh ; and Bateman's 'Excise Officer's Manual,' 12mo., London.

Between the sliding-rule and the book of logarithms comes the card of four-figure logarithms, published by Messrs. Taylor and Walton (explained in the 'Companion to the Almanac' for 1841), to which has been added a similar card for sines and tangents. A sliding-rule, which would *in all parts* compete with these tables in accuracy must have a radius of from 8 to 10 feet, and would be unmanageable. At what length the card begins to be more easily used than the rule we cannot determine, but we should suspect that the former would be preferable to a rule of four feet radius. We have found the rule of 24 inches extremely useful in checking the material figures of more minute calculations, particularly when there are many divisions by the same divisor.

The history of the sliding-rule, had it ever been properly given, would be matter for a few lines of our work, in the way of abbreviation and reference. As it is, we have not only to establish the main points, but also to point out a specimen of the manner in which the account of early English science has been written. Harris's 'Lexicon Technicum' (1716) informs us that sliding-rules 'are very ingeniously contrived and applied by Gunter, Partridge, Cogshall, Everard, Hunt, and others, who have written particular treatises about their use and application.' Stone's 'Mathematical Dictionary' (1743) has the same words. Dr. Hutton ('Math. Dict., 1815) informs us that they are variously (not ingeniously) contrived and applied by different authors, particularly Gunter, Partridge, Hunt, Everard, and Coggleshall. Other writers repeat this sentence in their own ways, and the summing up is this :—the recognised history of the sliding-rule consists in the names of five persons ; all our best English authorities are unanimous in stating that these men 'contrived and applied' sliding-rules, either ingeniously or variously ; but to the credit of this century be it spoken, that it was our historian who altered the chronological order, and spelt Coggleshall's name right : had it not been for the research of Dr. Hutton, it might have been Cogshall to this day.

We now go on to something more like history. It is generally stated that Gunter invented the sliding-rule. This is not correct ; Gunter neither invented this rule nor wrote about it ; and though he was the first (*On the Crosse-staffe*, book i., cap. 6) who used a logarithmic scale, it was in the manner described at the beginning of this article, compasses being used to make the additions and subtractions. Gunter's rule is used up to the present time, under that name, in the navy, without any slides.

The real inventor of the slide was OUGHTRED [BIOG. DIV.], who was also the first writer upon it. He was a man who set but little value upon instrumental aids, unless in the hands of those who had previously learned sound principles, which (as we have seen) he himself testifies. In the year 1630 he showed it to his pupil William Forster, who obtained his consent to translate and publish his own description of the instrument, and rules for using it. This was done under the following title : 'The Circles of Proportion and the Horizontal Instrument,' London, 1632 ; followed, in 1633, by an 'Addition, &c.,' with an appendix, having title, 'The Declaration of the two Rulers for Calculation.' The following extract from W. Forster's [*] dedication to Sir Kenelm Digby will explain the whole :—

"Being in the the time of the long vacation 1630, in the Country, at the house of the Reverend, and my most worthy friend, and Teacher, Mr. William Oughtred (to whose instruction I owe both my initiation, and whole progresse in these Sciences), I upon occasion of speech told him of a Ruler of Numbers, Sines, and Tangents, which one had bespoken to be made (such as is usually called Mr. Gunter's Ruler), 6 feet long, to be used with a payre of beame compasses. He answered that was a poore invention, and the performance very troublesome : But, said he, seeing you are taken with such mechanicall wayes of Instruments, I will show you what devises I have had by mee these many yeares. And first, hee brought to mee two Rulers of that sort, to be used by applying one to the other, without any compasses : and after that he shewed mee those lines cast into a circle or Ring, with another moveable circle upon it. I seeing the great expeditenesse of both those wayes, but especially of the latter, wherein it farre excelleth any other Instrument which hath bin knowne ; told him, I wondered that he could so many yeares conceale such usefull inventions, not onely from the world, but from my selfe, to whom in other parts and mysteries of Art he had bin so liberall. He answered, That the true way of Art [†] is not by Instruments, but by Demonstration : and that it is a preposterous course of vulgar Teachers, to begin with Instruments, and not with the Sciences, and so instead of Artists, to make their Schollers only doers of tricks, and as it were Juglers : to the despite of Art, losse of precious time, and betraying of willing and industrious wits unto ignorance, and idlenesse. That the use of Instruments is indeed excellent if a man be an Artist : but contemptible, being set and opposed to Art. And lastly, that he meant to commend to me the skill of Instruments, but first he would have me well instructed in the Sciences. He also shewed me many notes, and Rules for the use of those circles, and of his Horizontall Instrument (which he had projected about 30 yeares before) the most part written in Latine. All which I obtained of him leave to translate into English, and make publique, for the use and benefit of such as were studious, and lovers of these excellent Sciences."

Oughtred gave his right in the invention (so soon as it was settled to be published) to Elias Allen, a well-known instrument-maker, near St. Clement's Church, in the Strand. In walking to and fro from his shop, he communicated his invention to one Richard Delamain, a mathematical teacher whom he used to assist in his studies. This Delamain not only tried to appropriate the invention to himself, but wrote a pamphlet of no small scurrility against Oughtred, which the latter answered in an 'Apologeticall Epistle' fully as vituperative ; which epistle was printed at the end of W. Forster's translation. It contains some quantity of biographical allusion, and must not be forgotten by a mathematical historian of the times. W. Forster's work was republished in 1660, by A. H. (Arthur Haughton, another pupil of Oughtred), with Oughtred's consent, but the dedication and epistle were omitted.

The next writer whom we can find is Seth Partridge, in a 'Description, &c. of the Double Scale of Proportion,' London, 1685. He studiously conceals Oughtred's name : the rulers of the latter were separate, and made to keep together in sliding by the hand ; perhaps Partridge considered the invention his own, in right of one ruler sliding between two others kept together by bits of brass. Coggleshall's ruler was made in both ways, that is, with the rulers attached and unattached ; it appears to have come in at the end of the 17th century. Since that time several works have been written, and various modifications of the ruler proposed. Ward ('Lives of Gresham Professors') is incorrect in saying that Wingate carried the sliding rule into France in 1624 : it was Gunter's scale which he introduced there. In fact the slide was little used and little known till the end of the century. Leybourn, himself a fancier of instruments, and an improver (as he supposed) of the sector, has 30 folio pages of what he calls instrumental arithmetic in his 'Cursus Mathematicus' (1690), but not one word of any sliding-rule, though he puts fixed lines of squares and cubes against his line of numbers in his version of Gunter's scale.

Finding so meagre an account on this matter in publications professedly mathematical, we did not at first think of having recourse to any others. When we had finished the preceding however, we thought of consulting the 'Biographia Britannica,' and there we found, in the middle of a very full life of Oughtred, the whole account of the invention of the sliding-rule, exactly as above, and from the same authorities. On looking at Dr. Hutton's account in the Dictionary, we perceive that he has either used this memoir or some copy of it; but without giving any information on the subject of the present article.

---

[*] The maker of this slide has them of various lengths up to 24 inches.

[*] This man must not be confounded with the Gresham professor of his name ; nothing more than his connection with Oughtred is known of him. The one whose name is so much connected with Gunter is Samuel Foster (died 1652), Gresham professor of astronomy.

[†] Here is the old use of the word art ; we should now say science. [SCIENCE.]

We shall conclude this article by some account of a new species of sliding-rule, invented by Dr. Roget ('Phil. Trans.' for 1815), which would be very useful in the hands of writers on statistics, and would sometimes save much trouble to the mathematician. The slide contains a common logarithmic line of two radii, each 10 inches in length. The fixed ruler has not logarithms, but logarithms of logarithms denoted by its spaces. For instance, reckoning from 10 (remembering that log log 10 = 0), the space from 10 to 100 is log log 100, or log 2, the same space as from 1 to 2 on the slide. And since log log x is positive or negative, according as x is greater or less than 10, we have the *logologarithms* laid down on the left for numbers less than 10, and on the right for numbers greater. This instrument is constructed by Mr. Rooker, and in this manner: 10 is on the middle of the upper ruler, which ends on the right at 10^{10}, or ten thousand millions; and on the left at 1·25. At the extreme right of the lower ruler we find 1·25 again, from which we recede to 1·0025 on the extreme left. The upper and lower rulers are so adjusted that from the end of one to the beginning of the other it is exactly two radii, so that a setting on the upper ruler applies also to the lower, but it may be necessary first to slip the slide a whole radius forwards or backwards, in the manner described in the preceding part of the article. And here again the meaning of the reading on the slide must frequently be determined by common sense applied to the problem.

When 1 on the slide is placed opposite to a on the ruler, we have b on the slide opposite to a^b on the ruler. Or using the preceding rotation—

$$\begin{array}{lll|ll|ll} \text{Rule} & a & a^b & a & \sqrt[b]{a} & a & \sqrt[b]{a^c} \\ \text{Slide} & 1 & b & b & 1 & b & c \end{array}$$

The approximations of this rule are equally easy whether applied to fractional or integer exponents, and Dr. Roget justly observes that it gives a much better idea of the rapid increase of powers than simple reflexion. It is so little known even to mathematicians, that we put down some of its results as specimens of its powers. Set 1 on the slide opposite to 3·14 on the rule, and we find for the approximate powers of this number by simple inspection 9·85, 31, 97, 300, 960, 3000, 9500, 29,500, 93,000, &c. The square root is 1·772, the cube root 1·463, the fourth root 1·331, the fifth root 1·257. We must now change the slide, as above directed, so as to put it in connection with the lower scale, and the proceeding roots are 1·215, 1·178, &c. All questions of increase of money, population, &c., are in this manner reduced to simple inspection, and very easy trial gives that approximate solution of exponential equations which the mathematician must find before he applies his more extensive methods. Thus, to form the table of logarithms in Scale the base of which is $\sqrt[12]{2}$:—Set 12 on the slide opposite to 2 on the ruler, and the table is ready, as far as the instrument will give it. Thus, opposite to 3, 4, 5, &c., we find 19·0, 24, 27·9, 31·0, 33·7, 36·0, &c., almost exactly as in the table cited. It is also worth notice that each division of the upper fixed ruler answers to the hundredth power of the division directly beneath it on the lower fixed ruler. Thus, wishing to know what effect would be produced in 100 years upon a population which increases 3·46 per cent., we set unity to 1·0346 on the lower scale, and find at once 30·025 on the upper ruler, being the number by which the present population must be multiplied.

The late Mr. Woollgar (to whom we were indebted for much information in this article, and who made a particular study of the sliding-rule) carried to a considerable extent the principle of making the slide or the rule (no matter which) bear, not the logarithms of the numbers marked on its graduation, but those of the values of a function of those numbers ('Mechanics' Magazine,' No. 849, vol. xxxii.) Let a slide be so graduated that the interval from a given point to the graduation x represents log ϕx. When x is then ascertained (by the common scale, if necessary), the formula $a\phi x$ is immediately deduced from the common scale and the new slide. Nor need there be a new slide: for any scale being laid down in the groove, the common slide, by having its end made to coincide with one or another division of the scale in the groove, may be rendered capable of answering the purpose of a new slide.

We long since obtained from Paris a circular logarithmic scale in brass, altogether resembling the one figured and described in the preceding part of this article, with the addition only of a clamping screw. This instrument, the scale of which is 4½ inches in diameter, is so well divided that it will stand tests which the wooden rules would not bear without showing the error of the divisions. But here arise disadvantages which we had not contemplated. In the first place, no subdivision can be well made or read by estimation, unless the part of the scale on which it comes is uppermost or undermost, which requires a continual and wearisome turning of the instrument. In the next place, to make the best use of it, and bring out all its power, requires (we should rather say renders worth while) such care in setting and reading, as, unless a microscope and tangent screw were used, makes the employment of the four-figure logarithm card both shorter and less toilsome. For rough purposes, then, a wooden rule is as good; for more exact ones, the card is better. We made a fair trial of both on the tables in Solar System, and are perfectly satisfied that though the French brass arithmometer did, with great care, bring out the results required, the four-figure card did the work more easily. But, had we wished to abandon two or three units in the last places of figures, there would then have been no doubt that the instrument would have been the easier of the two: but then a straight wooden rule of the same radius would have done quite as well, and been more convenient still. ('Mechanics' Magazine,' No. 949.)

SLIDING SCALE. [Slide or Sliding Rule.]

SLING, an instrument with which stones or other missiles may be thrown to a great distance. In its simplest form the sling consists of a thong of leather, or a piece of cord or some woven fabric, both ends of which are held in the hand of the slinger. The stone or missile is placed in the fold or double of the thong, which is made wide at that part, and sometimes furnished with a slit or socket for the purpose of holding it; and the sling is then whirled round to gain an impetus. When a sufficient degree of centrifugal force is thus generated, the slinger allows one end of the thong to escape, and the stone, being thereby released, flies off with considerable velocity. In the hands of an expert slinger, this instrument may be made to project missiles to a great distance, and with surprising accuracy.

The simplicity and portability of the sling, and the facility with which supplies of ammunition for it might be obtained, led to its extensive use among the ancients as a weapon of war, as well as for other purposes. Its common use among the Jews is intimated by several passages of scripture. Several ancient paintings represent the use of the sling at an early period by the Egyptians. Some of these are given by Wilkinson. In the Greek and Roman armies the light troops consisted in great part of slingers, who were called *σφενδονῆται*, or *funditores*, from *σφενδόνη*, and *funda*, the Greek and Latin names of the weapon. The Carduchi, according to Xenophon, annoyed the retreating army of the Ten Thousand by their powerful slings. ('Anab.', iv. 1, &c.) There are no slingers mentioned in Homer; and the word which usually means sling (*σφενδόνη*) occurs only once ('Iliad,' book xiii., line 599), and then not in the sense of sling, but in the primary sense of the word, which means a broad band or bandage. This passage has sometimes been strangely misunderstood. The sling is not mentioned by Herodotus; and it is an error to assign the use of it to the Persians, for which there appears no evidence but a loose expression in Diodorus (xviii. 51), where he speaks of 'Persians, bowmen and slingers, five hundred." The natives of the Balearic Islands attained the highest reputation for their skill in its management; which is attributed to their custom of teaching their children, while very young, to wield it, and forbidding them, it is said, to taste their food until they had dislodged it from a post or beam by means of a sling. Besides stones, leaden plummets, cast in moulds, were used as projectiles for the sling. These, which were called *glandes*, or *μολυβδίδες*, were of an elongated spheroidal form; somewhat resembling that of olives or acorns. They have been often discovered in various parts of Greece, and frequently bear on one side a figure of a thunderbolt, and on the other side either the word ΔΕΞΑΙ (take this), the name of their owner, or some other inscription or device. Some of these were of considerable size, weighing as much as an Attic pound, or 100 drachmæ. Fireballs also have been thrown by slings. Some of the slings used by the ancients were managed by more than one cord; one, two, or three being used, according to the size of the missiles to be thrown.

The sling was long used in England. The Saxons certainly used it, and seem to have been skilful in its management. Besides the ordinary sling, they used one attached to a staff or truncheon three or four feet long, wielded with both hands. This kind of sling, with which large stones were thrown, appears to have been used principally in sieges and in naval warfare. It is represented in an old drawing, supposed to be by Matthew Paris. Slingers formed a part also of the Anglo-Norman soldiery; and the sling had not fallen into disuse as a military weapon at the commencement of the 15th century The use of the sling may now be considered obsolete in this country as an offensive weapon.

(Wilkinson's *Manners and Customs of the Ancient Egyptians*, first series, vol. i.; Strutt's *Sports and Pastimes*.)

SLIP, *Earthwork*. When in an embankment, or cutting, the materials move laterally in consequence of some dynamical action, they are said to slip, and they do so occasionally under circumstances which can only be overcome with great difficulty, and at great expense. Slips occur either when heavy loads are placed on incoherent materials, which under such circumstances are simply displaced; or they occur when the earth is of such a nature as to absorb so much water as to become a semi-fluid mud; or when there are intercallated between more impermeable strata beds of sand, or other open materials susceptible of being removed. The former of these sources of danger can easily be avoided by carrying the foundations of the intended load to such a depth as to ensure their not exerting any detrusive force; the latter sources of danger are far more complicated, and they require to be dealt with very carefully, on account of the numerous considerations attached to the change of state the materials often assume before they get into motion.

Uniformly permeable materials, such as broken stones, gravel, or shingle, are not exposed to slip after they have once taken their angle of repose, because the gravity of the separate stones is sufficient to keep them in their places whilst the water falling upon their exposed surfaces is percolating through them. Very fine sands, however, are able to be rendered semi-fluid under some conditions, and they then have no angle of repose, and are able to spread in every direction. Some clays, such as the Oxford clay, the gault, and the London clay, which seem to have originally been the alluvial muds of marine estuaries, subsequently dried and consolidated, are susceptible of absorbing again quantities of water able to bring them into their original state; and it seems, from the experience of our railway and canal engineers, that many years must pass before cuttings executed in those formations attain permanent conditions of stability. Instances have been known in which slips have taken place in the Oxford clay formation when the slopes have been even 10 to 1 (10 base to 1 in vertical height); and the New Cross cutting of the Brighton Railway, in the London clay, slipped in the winter 1860-61, although it had formed part of the cutting for the old Croydon canal executed nearly sixty years since. Slips, it may be added, occur in undisturbed natural deposits exposed to the action of the sea, or of running water, and the same class of accidents, above described as occurring in the cuttings and embankments executed by the hand of man, occasionally happen in consequence of the action of the ordinary laws of nature. When they do happen in coal mines, or in analogous positions, owing to the interference with the lateral support of the strata worked through, the slips are technically known under the name of "creeps," and they constitute by far the most dangerous, because the most irresistible, of the accidents to which coal mining is exposed.

As slips are principally attributable to the effects of water upon the materials concerned, it must be evident that the only method of preventing or remedying them must be to establish a perfect system of drainage in order to carry off superficial waters without allowing them to soak into the ground so as to dilute the soluble materials, or to set in motion the more minute particles of the intercallated permeable strata. The mode usually adopted near London in dealing with the earthworks to be formed around, or for the support of, waterworks, where of course slips would be of very serious importance, is to carry up the embankment in layers, alternately of the clay in its natural state, and of the clay after having been burnt in a heap; vertical dykes or trenches filled in with burnt clay are carried from the top to the bottom of the bank; and the top is dressed off with the longitudinal and transverse inclinations required to throw the rainwater into a series of surface drains. Theoretically this system is the one to be aimed at in all such works, but it is too often the case that the cost of the precautions it involves induces constructors to neglect some of them; and again it may happen that the materials of the banks are exceptionally impermeable, and thus justify a more economical mode of treatment. Nevertheless, it must be considered that, especially upon ground having a transverse fall, an embankment formed of the London clay is always exposed to slip, unless it should have been executed in some such manner as the one above mentioned. Broken stone or broken chalk may be used instead of the burnt clay; but the condition to be aimed at in the application of those materials is that they should be perfectly permeable, and that the water they may remove should have a free outlet. In deep cuttings, the experience of the New Cross section of the Brighton line proves that the London clay, as it exhibits itself there, will not stand with slopes of less than 4 to 1, even when a good system of superficial drains has been executed. In no case will the stiff blue clays stand with slopes of less than 2 to 1, without giving rise to numerous slips; and those accidents can hardly be prevented, unless the inclination of the slopes is made in the ratio of 3 to 1. An essential precaution to be taken before establishing an embankment of clay is to clear its seating from the vegetable mould which might be originally there, and to provide efficient lateral drains, in order to prevent any land waters from finding their way under the embankment. In order to prevent lateral displacement, or slipping on the bed, on sloping ground, it is frequently the case that toothings are cut in the natural surface, for the purpose of increasing the friction, and thus of opposing the tendency to slip.

The earthwork at the back of retaining walls is frequently so much saturated with water that it has very little more consistency than that fluid itself has; and it is therefore necessary, in order to resist its tendency to slip, to calculate the strength of the wall upon the supposition that the wall is intended to resist the pressure of a semi-fluid mass denser than water. In many places near London, and in seaports upon alluvial deposits, the best rule seems to be to make the thickness of the walls equal on the average to half their height. This rule will hold good with most deliquescent clays, such as the gault, Oxford clay, the clays of the carboniferous series, &c.; all of these are in fact as much exposed to slip as the London clays, from which the previous illustrations have been principally derived.

SLIP, *Ship-Building*. The slips used for ship-building are inclined surfaces (the upper parts of which are kept constantly above the water line, and the lower parts are carried to the requisite depth below the water) for the purposes of building and launching the hull, either into tidal or constantly deep water. They may be placed either in an inclined direction to the line of the shore or normally to it, according to the width of the piece of water into which the ship is to be launched, to the set of the currents, or to the exposure of the situation; and there must always be a clear space of deep water beyond the lower end of the slip, equal to at least twice the length of the vessels to be built on it. In most government ship-building yards several slips are grouped together, in which case they must be separated by level platforms of sufficient width to allow the carpenters to prepare the timber required for the framing, or by platforms of 60 to 100 feet in width, inasmuch as from 30 to 50 feet are required on each side of a ship for this purpose. Wherever it is possible so to place a series of slips, they should be so arranged as to ensure an equal degree of light and heat to the sides of the ships built upon them; for, on account of the length of time a ship is usually upon the stocks, the materials, which might happen to be exposed to a considerable excess of either of those actions, would be likely to have marked differences in their specific gravities at the period of launching; or, in other words, the weights of the two sides of the ship might be very different. The depths of water it has been found advisable to secure over the extremity of the slips at the moment of launching a vessel are considered to be as follows:—

For a first rate three-decker . . .	18 ft. 0 in.
For a two-decker	14 ft. 9 in.
For a frigate	10 ft. 6 in.
For a corvette or small craft . . .	8 ft. 3 in.

But in all cases it is assumed that the hulls are launched "light." The depths, moreover, are calculated by measuring from the under side of the keels; and as the latter are usually placed in a groove of about 3 feet wide by 16 or 18 inches deep, in the centre of the slip, it is only upon the line of this groove that the above-mentioned depths are indispensable.

The sides of a building-slip, respectively on the right and left of the groove for the keel, must in all cases be precisely similar; and, wherever possible, they should be made rectilineal in their transverse section. The longitudinal section should also be rectilineal; and it would appear that the angle of inclination should vary with the weight of the vessel upon the stocks: thus, for three-deckers, an inclination of $\frac{1}{10}$ is necessary, whereas, for frigates, an inclination of $\frac{1}{12}$, or even of $\frac{1}{14}$, would suffice. Very small craft—such as sloops, yachts, &c.—are most conveniently launched, however, from slips having very steep inclinations. It is usual to make the lower immersed ends of the slips for the construction of large vessels about 150 or 160 feet long beyond the end of the portion devoted to the stocks and hull, the latter portion being at the present day made about 300 feet long; so that a building-slip for a large man-of-war is now usually from 450 to 500 feet long at a maximum. The width of the sides of the slips, measured transversely to the line of the keels, should never be less than from one-third to one-half of the maximum breadth of the vessels to be built upon them, and in practice it seems to range between 22 and 28 feet. The platforms on which the timber is worked by the sides of these planes are raised above their level; but in so doing it is essential to observe—1, that any rain-water falling upon them must be carried away from the slip; 2, that no interference must be allowed with the free circulation of air round the hull; 3, that the shores, either for building or for launching, should have a sufficient width of base; and 4, that the vessel, in leaving the ways, should have sufficient space to be able to sway freely within moderate limits.

The majority of the building-slips in English dockyards are at the present day covered, at least in the length occupied by the vessels ordinarily built on them. Of course the dimensions, in length, breadth, and height, of such structures must be regulated by the dimensions of the vessels themselves; and as naval architecture appears at the present day to be in course of change in all these respects, it may be dangerous to pretend even to state any general laws on the subject. It may suffice, then, to mention that, for the old class of 120-gun ships, the roofs over the slips were usually made about 300 feet long by 110 feet clear span between the points of support, and the ridge was usually kept at about 120 feet above the depression for the keel; the framing of the roof must be kept about 6 feet, at least, above the loftiest portion of the vessel; and the opening at the end, through which she has to be launched, must have at least the same amount of clear space in all directions; the side supports of the roof must be placed at such distances apart as to allow the framing which may be put together on the side platforms to be set on end before being carried to their definite positions, and in some of the best slips they are placed at intervals of from 30 to 40 feet. In fact, the conditions to be attained by the roofs erected over building-slips are, that the work and the workmen should be at all times protected from the inclemencies of the weather, whilst there must be an efficient ventilation and a good distribution of light, together with facilities for the transport and hoisting of the materials. The use of iron for ship-building will no doubt greatly modify the details to be adopted in all these matters; but the principles of effectually protecting the whole structure, and of admitting the undisturbed execution of the various manipulations, must remain unchangeable. It would seem, indeed, that iron ships required to be protected from the effects of the atmosphere during their construction even more carefully than wooden ones; and "the fleet of the future" may tax the skill of our constructors to cover their hulls whilst on the slips even more than the old liners have done. Amongst the most important and the most successful covered building-slips, those erected at Woolwich and Deptford may be specially cited.

Some years since, Captain Morton patented what he called "the patent slip," for the purpose of hauling vessels on shore in positions and under circumstances wherein it was requisite to examine and repair their bottoms, and wherein it was either impossible or inexpedient to take the vessels into graving-docks. This slip consisted of the usual inclined way passing down under the high-water line. Upon this way, a platform on rollers, with proper stops, ratchets, and brakes, bearing also iron cradles adapted to receive the ship's sides, was made to work, by means of a steam-engine, in such a manner as to allow the platform to pass under the ship at high-water. The ship subsided into the cradles with the falling tide; and being then carefully wedged into them, it was hauled up upon dry land to be treated as required. Slips of this description have been found to answer remarkably well for vessels of less than 400 or 500 tons burden; beyond those dimensions, the weight of the hulls becomes too great to be economically dealt with in this manner, and it becomes necessary either to resort to the use of the hydrostatic or floating docks, or to take the vessel into a graving-dock, if it should require repairs. Morton's slips are to be found at most of the second-rate ports on our coast, and they are of extreme utility for our coasting-trade.

The most important consideration with respect to the construction of building-slips is, that the floor should remain rigid under any possible load brought upon it; for any inequality in the rate of settlement would not only increase the difficulty of launching, but it might very possibly produce a deformation of the lines of the vessel. As ship-building almost necessarily takes place on the sea-shore, or on the banks of rivers flowing over alluvial deposits, there are very few occasions in which the natural foundations are sufficiently resisting; and it therefore becomes necessary to resort to the use of artificial foundations of some of the descriptions already mentioned. It is under the line of the keel that the greatest strain occurs, and that portion of the foundations must be treated with the greatest attention.

SLUICES. A contrivance used in hydraulic engineering for the purpose of closing, or of regulating the passage of water from one level to another, is properly speaking called a *sluice*, although occasionally when the door itself is upon hinges, or is made to work by machinery, the closing door is called a *vane*, or a *valve*, and the leading passage only is called the sluice. By extension, the word *sluicing* has also been applied to the operation of allowing a large body of water to escape through a sluice with great velocity, for the purpose of removing the light alluvial matters which may accumulate in the outer harbours of a sea-port, or in any analogous position. Properly speaking a lock-gate is a species of sluice; but the usages to which that class of machinery is applied are of so great importance as to have rendered it advisable to treat of its construction and details under the head of CANAL.

As was said under that article, the discharge through a sluice of the ordinary form, (that is to say, of a rectangular section, and without any provision for the effect of the contraction of the fluid vein,) is usually calculated by the formula $Q = ms\sqrt{2gH}$, in which $m =$ a coefficient of 0·625, when only one sluice is used, and of 0·548, when two sluices are used and their streams can meet within a short distance of their points of outlet. This formula, it must also be added, only applies when the sluice discharges into the open air, and there is no head of water on the down side, and it becomes $Q = ms\sqrt{2g\ (H - H')}$ when there is such a head; H representing the depth of water on the up side, and H' the depth on the down side; in both formulæ s represents the area, and g, the accelerating force of gravity. By forming the commencement of the sluice in the manner described by Venturi in his remarks on the effect of *ajutages*, the discharge of single sluices may be increased to such an extent as to make the value of $m = 0{\cdot}984$; but unless the mouth of the sluice be executed in ashlar masonry, or in cast iron, it would be difficult to effect this improvement; and in practice it is rarely attempted. Canal sluices, or sluices for the irrigation or drainage of land, rarely work under great heads of water, and they do not therefore require any very extraordinary precautions in the construction of their channels, or of their machinery; but in the sluices used for scouring harbours, and occasionally in those used for drawing off the water for town supplies, the velocity of efflux renders it necessary to build some portions with particular care. For instance, it is by no means rare to meet with scouring-sluices working with a head of water equal to 16 or 18 feet, and the variable head usually allowed upon the outlet of town reservoirs is equal to 14 feet; under these circumstances the water rushes out with such force as to be able to tear up the surfaces it comes immediately in contact with, and it is therefore indispensable that the tail walls of open sluices, or the materials of closed ones, should be of the most resisting character. The apron at the tail end, and the leading passage of the sluice up to the valves, are in almost all cases executed either in solid masonry, or in iron pipes, to which the framework of the valves is fixed.

In small land sluices, discharging water into tidal rivers, the outlets are frequently closed by flaps hung in such a manner as to open when the head of water on the inside exceeds that upon the outside, but to close directly the outside head preponderates. These flaps, however, are easily liable to derangement by the interposition of extraneous bodies; and they are not therefore used when it is important to shut out external waters under all circumstances. In the latter cases valves working in close grooves, and raised by machinery worked by hand, or self-acting, must be resorted to; and if the area of the water-way should be large—as in the case of scouring-sluices—doors must also be employed. Valves, in fact, are the most suited for closed channels, or aqueducts; turning doors for large areas of water: the former description of machinery is well illustrated in the various works mentioned under WATER SUPPLY; and the latter, in Sganzin's 'Cours de Construction,' and Minard's 'Travaux Hydrauliques des Ports de Mer.'

The question as to the advantages of scouring-sluices for the purpose of removing accumulations in harbours, is one upon which opinions are much divided: for although when the water from the scouring reservoirs is allowed to escape with considerable velocity, it is able to act very energetically upon the materials it may meet in the confined part of the channel; yet directly the stream passes the heads of the jetties it must lose its velocity, and consequently its transporting power. Unless, therefore, there should exist a littoral current able to carry forward the matters scoured out from the inner harbour, a bar must eventually be formed in the zone of still water caused by the interferences of the respective forces of the sluice-waters and of the tides. At the present day, the tendency of modern engineering is to abandon the use of scouring-sluices, and to trust entirely to dredging for the removal of the alluvial matters carried into the ports exposed to that inconvenience. But as there are many occasions in which it might still be advantageous to resort to the use of sluices, it may be as well to add that the principles to be observed in their construction are:—1st. To make the impounding reservoirs of such forms as to insure the prompt discharge of the whole quantity of water they may contain, for which purpose a semicircular basin, with the outlet upon the centre of the chord line, is the most advantageous; 2nd. To make the outlets as large as possible, and to continue the outfall channel as far as may be necessary to conduct the stream, with its full force, against the obstacle to be removed; and 3rd. To place the outlet of the sluices as near to the head of the jetties as may be. The scouring-sluices of Dover, Calais, Dunkirk, Ostend, and the great sluices of Catwyck, through which the waters of the old Rhine are discharged into the German Ocean, are perhaps the most remarkable works of their several descriptions in existence. The reader will find much information on this subject, as also upon the construction of sluices, sluice-gates, valves, &c., in Wiebeking, 'Allgemeine Wasserbaukunst;' Rennie, 'On Harbours;' in Weale's 'Quarterly Papers on Architecture;' Sim's 'Public Works of Great Britain;' D'Aubuisson's 'Hydraulique,' &c.

SLUR, in Music, a curved line (⌒) more or less extended, as may be required, drawn over two or many notes. If placed over two notes on the same line or space, it signifies that the second is not to be repeated, though to be held out its due time. When drawn over notes on different degrees, it signifies that they are to be *legato*, that is, tied—played in a smooth blending manner. This character is sometimes called a *bind*, and also a *tie*.

SMALL-POX (*Variola*). It is a subject of dispute whether this disease was known to the ancients, or whether it has originated at a comparatively recent date. Those who contend for its antiquity refer us to the account of the plague of Athens by Thucydides (ii. 46, &c.) which, they say, is as accurate a description of the leading symptoms of variola as could possibly be expected from any historian who is not a physician. Those who hold the opposite opinion call in etymology to their aid; the word *pock* or *pox*, they say, is of Saxon origin, and signifies a bag or pouch; the epithet *small* in England, and *petite* in France, were added in the 15th century. The term variola is derived from the Latin word *varus*, a pimple, or *varius*, spotted; and, according to Moore, the first authentic passage in which it occurs is to be found in the 'Bertinian Chronicle' of the date 961. The first author, however, who treats expressly of small-pox is Rhazes, an Arabian physician [RHAZES, in BIOG. DIV.] but even he confounded it with measles, and these two diseases continued to be considered as modifications of the same disorder till the time of Sydenham. Small-pox, when it occurs naturally, is preceded by the usual premonitory symptoms of eruptive fevers, such as rigors, pains in the back and loins, prostration of strength, loss of appetite, nausea, and sometimes vomiting, and, in young children, frequently convulsions. About forty-eight hours after the commencement of these symptoms an eruption of small, hard, red-coloured pimples makes its appearance about the face and neck, and gradually extends downwards over the trunk and extremities. The primary fever, as it is called, now lessens, but the pimples increase in size, and become converted into whey-coloured pustules with a depression in their centre. On the eighth day they are at their height, and on the eleventh the matter oozes from them and concretes into crusts, which fall off about the fourteenth day, leaving the skin of a brownish-red colour, and studded with slight depressions or pits. As the eruption travels from above downwards, the parts of the body successively attacked by it become affected with swelling, the mouth waters, and the voice is hoarse; when the incrustation has taken place, these symptoms subside, but a secondary fever commences, which is sometimes more severe than that which preceded the outbreak of the eruption. Small-pox, according to its severity, is distinguished by authors into two varieties, the *distinct* and the *confluent*, *variola discreta* and *confluens*. In the former, the pustules are few in number, well formed, and do not touch each other, and the fever is inflammatory, but mild; in the latter, the disease altogether is more violent, the eruption more general, and the pustules, small and unhealthy, run one into another. The fever likewise is greater, and rather of the typhoid character, is not mitigated on the appearance of the eruption, and is much aggravated at its termination; there is delirium, considerable prostration of the vital powers, ptyalism, inflammation of the fauces, and frequently diarrhœa. Petechiæ and an unhealthy exudation from the body often accompany this form of the disease. Among the mucous membranes, the larynx and trachea suffer much, and children often die of suffocation from this cause; the extent of mucous and of cutaneous inflammation, however, are not always necessarily proportioned to each other. Small-pox rarely attacks the same individual more than once, and, like measles and scarlatina, its consequences are sometimes more to be dreaded than the disease itself. During the secondary fever, an intense form of ophthalmia frequently sets in, which rapidly involves all the structures of the eye, and in the course of a few days destroys its entire organisation. Although it is not common to have both eyes thus affected, still a large proportion of the blind at our public institutions owe their misfortune to this disease. Pleurisy, consumption, scrofula, obstinate diarrhœa, and a fetid discharge from the ears attended with more or less deafness, are the principal diseases liable to result from a severe attack of small-pox. The immediate cause of this disease is a peculiar miasm or poison received into the system from an individual labouring under the same affection, and it is said to make its appearance in from twelve to fourteen days after exposure to the contagion; when, however, it is communicated by inoculation, it appears on the seventh or eighth day. Instances are recorded of mothers who were exposed to the infection of small-pox, communicating the disease to the fœtus in utero, without being themselves affected by it; and, what is equally remarkable, women suffering from small-pox during pregnancy, have brought forth healthy children, who did not take the disease till they were inoculated. Small-pox is frequently epidemic, especially in the spring, and, like all other epidemics, those who are first attacked by it suffer the most severely: it is observed also to be greatly influenced by certain conditions of the atmosphere.

Small-pox can be communicated by inoculation with the matter of its pustules, and the resulting disease being rendered milder by this operation, it was formerly much practised to guard the individual against a spontaneous attack; since, however, the introduction of vaccination by Dr. Jenner, the practice has been deservedly abandoned. Vaccination was supposed by its discoverer to secure the individual permanently and effectually from the contagion of the small-pox; more extended experience has proved, that although it does not always prevent it, yet it so shortens its duration and moderates its violence, that a death from small-pox after vaccination is a rare occurrence. A difference of opinion prevails respecting the character of the eruption which occasionally appears after exposure to variolous infection in persons previously vaccinated. According to many, it is nothing more than chicken-pox; while others affirm that it is really small-pox, although modified by the controlling influence of the cow-pox. The truth appears to be, that "modified small-pox" resembles the chicken-pox in its mildness and duration, but differs from it in its originating from the "variolous germ," and in its power of communicating the true small-pox to others, as well by inoculation as by infection.

The history of the different epidemics of small-pox shows the mortality to be one in four of those attacked who had not been vaccinated; whilst of those who had undergone vaccination the proportion was not one in 450. From the register kept at the Small-Pox Hospital in London, it appears that the mortality at this institution is considerably greater than one in four, having averaged during the last fifty years 30 per cent., the extremes being 18 and 41. From the same source we learn that the greatest number of deaths occurs on the eighth day. Of 168 fatal cases, there died in the first week 32; in the second, 99; in the third, 21; and in the fourth and after, 16. The causes of death at these different periods are the following:—1st week, malignant fever; 2nd week, affections of the throat, and consequent suffocation; 3rd week, or during the secondary fever, febrile excitement, mortification of large portions of the integuments, pneumonia, pleurisy, or laryngitis; 4th, and following weeks, exhaustion, erysipelas, or some of the diseases before enumerated as liable to result from small-pox. It was formerly supposed that the eruption of variola was not confined to the skin, but invaded also the internal parts; this is not the case, the internal affections are simply inflammatory, and do not partake of the specific character of the cutaneous disease.

No peculiar plan of treatment is required for small-pox; it is that of ordinary fever: cleanliness, free ventilation, an attention to the strength of the patient, and a watchfulness against accidental complications, are the principal points to be kept in view. During the eruptive stage of the disorder, the bowels should be kept moderately open by saline aperients, and the occasional exhibition of a mild mercurial. The temperature of the skin may be regulated by cool air, or by sponging it with tepid vinegar and water; if there should be much unpleasant effluvium from the surface of the body, washing it with a weak solution of one of the chlorides will be found to correct this. It has been recommended by some writers, and has been long a practice in Eastern countries, to pierce the pustules with a fine needle; this procedure, it is said, lessens the violence of the secondary fever, and prevents pitting. M. Serres, with the same object, directs the application of lunar caustic to the pustules on the fourth day. As a general rule, we should say that venesection is not admissible at any period of small-pox; indeed we have no hesitation in affirming that some of the severest consequences of the disease may be averted by a judicious employment of measures of an opposite tendency to blood-letting. The sloughing of the integuments, and the intense ophthalmia, rapidly terminating in entire loss of vision, are eminently connected with an enfeebled and cachectic state of body; and the best mode of averting these evils is to have recourse early to those remedies which are most efficacious in arresting their progress. Hence quinine, combined with the mineral acids, sarsaparilla, wine, brandy, if the powers are much reduced, and animal food, if the patient can eat it, must be perseveringly administered. It may not be out of place here to mention that the character of the ophthalmia termed *variolous* has only lately been pointed out to the profession by Mr. Marson of the Small-Pox Hospital. It had been supposed that the eye was lost in small-pox from one or more of the pustules of this disease forming on the cornea. Mr. Marson has shown not only that this never takes place, but that the loss of vision is attributable to ulceration or sloughing of the cornea, which comes on generally about the eleventh or twelfth day of the disease. The patient is nearly always in a state of great debility, and requires tonic medicines and nutritious diet to give him a chance of escaping from the destructive effects of this ophthalmia.

SMALT. A silicate of potash coloured by means of oxide of cobalt in various shades of blue, which being reduced to powder is used in painting and varnishing porcelain and earthenware, for imparting a blue colour to glass, and in various other applications in the useful arts. The manufacture, which is a curious one, is minutely described by Mr. Tomlinson, in a paper read before the Society of Arts, London, and inserted in the 'Pharmaceutical Journal' for April, 1851. The materials are carefully prepared, and are melted in pots in the glass furnace, with occasional stirring. The combination of the materials by melting or smelting gives the origin of the word smalt from the German, *schmelzen*, "to melt," or the substantive *schmelz*, which means "enamel." Smalt or smalts is called also *schmelz* or *schmalz-blau*.

When the glass attaches itself to the workman's rod, and can be drawn out into threads, it is ready for pouring. The glass gall or sandiver is skimmed off, and the several metallic impurities of the cobalt subside; the latter being afterwards separated, form an article which is known in commerce by the name of *speiss*. It is variable in its composition; but may contain cobalt, nickel, iron, arsenic, bismuth, and silver. The blue glass is taken out of the glass pots in iron ladles, and poured into water in order that it may be readily pulverised. After this it is crushed at a stamping mill, sifted to the size of ordinary sand, and then ground in a mill between horizontal granite stones for from four to six hours. The powder thus produced is transferred to large vats of water, and in a few minutes a separation of particles takes place, the heaviest, or those richest in cobalt form a deposit, which constitutes one of the commercial varieties of smalt, known as *azure*, *coarse blue*, or *streu blau*. The number of minutes required to form this deposit varies with the season, it being somewhat longer in winter, when the water is colder and denser than in summer. The water above the deposit, holding finer particles, is drawn off into other vats and allowed to subside for a time, varying from three-quarters of an hour to an hour and a half, according to the quality of powder required. The term *farbe* or "colour" is applied to these deposits. The water is again drawn off into reservoirs and allowed to remain for an indefinite length of time, the deposit being known by the name of *eschel* or "blue sand."

The colours thus obtained are all again subjected to the action of water—*washing over* or *elutriation*, as it is called,—before they are fit for the market. "Each deposit is agitated in tubs abundantly supplied with water, and is then left to subside for a length of time, which experience has taught will produce the particular variety required. During the subsidence, any floating impurities are separated by means of a fine horse-hair sieve. The water is then carefully decanted off into another vessel; the deposit just formed is treated with fresh water if necessary; and all these waters in their turn, on being drawn off, deposit different varieties of smalt, either in the form of farbe or eschel." The various precipitates being taken out of the vats and drained are placed on shelves in a warm room or they are dried spontaneously in an airy loft. The hard masses thus formed are crushed and sifted, placed in a hot room with occasional stirring, and when dry are taken to a room in which are arranged a number of squares containing the different shades of smalt with their numbers. The sorting is followed by a final sifting, and the smalt is packed in small casks of half a hundred weight each. The powder is moistened with a little water to prevent waste, and the cask is marked with the name of the shade.

It may be remarked that artificial ultramarine [ULTRAMARINE] has superseded some of the uses for which smalt was formerly in large demand.

SMELLING SALTS. [AMMONIA.]

SMELTING. The processes of smelting, or extracting metals from their ores, are described under the names of the principal metals, such as COPPER; LEAD; METALS; IRON; &c.

SMILACIN. ($C_{16}H_{15}O_6$ or $C_{18}H_{15}O_6$). *Salseparin. Pareglin.* A peculiar principle found in sarsaparilla (*Smilax Sarsaparilla*). It exists in the form of colourless needles, is inodorous, very soluble in water and in alcohol, when boiling, but less so when cold. It dissolves in ether and volatile oils; the fixed oils dissolve it sparingly.

Smilacin dissolves in weak acids and alkaline solutions, and separates from them unaltered when they are neutralised. Nitric acid partly decomposes it. Sulphuric acid colours it first deep red, then violet, and afterwards yellow; water precipitates it unaltered.

SMILAX, *Medical Properties of.* Though, according to Dr. Hancock, but one species of this rather extensive genus yields the genuine sarsaparilla, it is quite certain that the roots of many are collected, and pass under that name in commerce. Most species of smilax are provided with spines, which has given origin to the first half of the name in the Spanish language, *zarza*, a bramble, and *parilla*, a vine, from its climbing or turning habit. Sarza has been adopted as the familiar name in the 'London Pharmacopœia,' which indicates *S. officinalis* (Humbt., 'Nova Genera et Species,' i.) as the source of the officinal article. This view is ably maintained by Dr. Berthold Seemann in the 'Botany of the Voyage of H.M.S. Herald,' London, 1852-57. The different kinds of sarsaparilla are better known by the course they follow in their progress towards European consumption, than by their botanical history. In describing them it seems best therefore to adopt their commercial names.

1. *Jamaica, or Red, Sarsaparilla.*—This occurs in bundles formed of the root alone, folded in a roundish mass, about a foot or more in length, and four or five inches broad. Each bundle is formed by the roots and rootlets (fibrillæ, or beards, as they are technically termed), without any portion of the rhizoma (or chump) or of the aërial stem. The roots are long, slender, about the thickness of a small quill, with a dark-brown furrowed or wrinkled bark. The bark is thick, easily separable from the ligneous part beneath. The ligneous part is of a light red, which assumes a deeper hue when moistened. It is easily split longitudinally, and has a whitish centre or medulla, containing more or less starch. But for the absence of medullary rays and of nodi, this root might be taken for the twigs of an exogenous plant, to which the structure of the smilaceæ approximates in several other points. A transverse section exhibits the cuticle and epidermis, which are separated from the inner or ligneous circle by a zone of cellular tissue; then the duramen, which presents the cut or open extremities of numerous ducts; and lastly, the medulla, or pith, in the centre. The duramen, though porous, is of a denser texture than that of the Honduras sarza. The taste is at first sweetish or slightly mucilaginous, then nauseous, resembling ipecacuanha, but not very acrid or bitter. No variety of sarza has any odour, but dirty or unwashed specimens have a faintly earthy smell.

The powder is a light reddish-brown, which, when triturated with water and tincture of iodine, changes to a blue, but of less intense depth than the Honduras sarza, indicative of a smaller proportion of starch in the former.

According to Mr. Pope ('Trans. Medico-Chir. Society,' xii., p. 349), "the whole medical efficacy resides in the bark; and the root, deprived of its cortical part, contains only pith and tasteless woody-fibre." The tasteless character of the wood renders this statement very probable. He further says: "The corticle part gives out nearly the whole of its virtues by cold infusion in distilled water, very readily to lime-water or water slightly impregnated with caustic alkali; and that boiling distilled water extracts all its virtues." He deems the quantity of extract yielded by any specimen the criterion of its excellence. Judged by this standard, the Jamaica sarza is manifestly the best. His experiments have been confirmed by those of Mr. Battley, and by Thubeuf. Jamaica sarsaparilla is the produce of the Spanish Main, and thence sent to Jamaica to be forwarded to Europe. Some has been cultivated in that island, but it is of inferior quality. The *Smilax officinalis* (Humbt.), which is conjectured to be the parent plant of the wild root, grows in New Granada, on the banks of the Magdalen river, near Bojorque.

2. *Lisbon, Para, or Brazilian Sarza.*—The term Lisbon sarza was also bestowed on the sort just described, for as Lisbon sarza was till lately most esteemed, the former on its first introduction was vended under that name. The true Lisbon sarza is the produce of *Smilax syphilitica*, which grows both in New Granada, on the river Cassiquiare, between Mandacava and San Francisco Solano, and in Brazil, on the Yupura and Rio Negro, by which last name it is sometimes designated. (Martius, 'Reise,' iii., pp. 1213, 1280.) The Indians collect it all the year round, dry it over a moderate fire, and tie it into bundles with the flexible stem of a plant called Timbotitica. To prevent its being attacked by insects, they hang it up at the gables of the houses, and sometimes gently smoke it. These bundles have a neat appearance externally, but the interior is filled up with the chump and other rubbish. The fibres vary in thickness from that of a straw to that of a crow-quill, with little beard, and fewer longitudinal wrinkles than the Jamaica sarza; the colour, a light, sometimes a dirty grayish-yellow, or reddish-brown colour, internally white; the cortical part mealy, including a thin cellular layer, which, with the duramen, is also white. Taste at first insipid, but on prolonged mastication a sort of acrid guttural taste, without bitterness, is experienced. This kind contains more starch than the Jamaica variety, and yields a paler infusion.

3. *Honduras Sarza* was the kind first introduced into medical practice, a circumstance which still leads many persons to prefer it. It generally comes over in very large bundles, weighing from one hundred to one hundred and fifty pounds, but sometimes in small round bundles. Each piece has the chump and the numerous roots proceeding from it. The chump is often two inches thick, woody, hard, and insipid. The roots are from two to four feet long, mostly thicker than those of the Jamaica or Lisbon kinds. The outer part is a dirty grayish-yellow, sometimes verging to brown or reddish. The cortical part is very easily separable from the ligneous; between the epidermis and the duramen is a thick white amylaceous layer, whence a large quantity of flour or starch falls when the piece is broken across; hence the term *mealy*, applied to this variety. A transverse section exhibits a great many cut extremities of ducts, which run parallel, and are so continuous, that air can be blown from one end to the opposite of a considerable piece. This kind has no odour, and the taste is at first merely starchy and insipid, but at last acrid and guttural. The rhizoma (or chump) is altogether tasteless. The fibres and the bark are rendered black by iodine; while the rhizoma is not affected by this re-agent. The decoction of the roots is changed to an intense blue by a solution of iodine. "A strong decoction of Honduras sarza forms a copious precipitate (starch) on addition of alcohol." (Pereira.)

4. *Vera Cruz Sarza* is not common in the English market, but is occasionally sold under the name of Lisbon sarza. It is the produce of *Smilax medica* (Schlecht), which grows abundantly on the eastern slope of the Mexican mountains. Externally the fibres are more furrowed than the Jamaica. The transverse section is denser in the young roots, and it is not mealy; there is little beard. The chump is always attached. It yields a deep-coloured decoction, which is unchanged by a solution of iodine. The sarsaparilla of the Caracas of French writers is deemed to be the Vera Cruz sort.

5. A kind called *Lima Sarza* is brought in considerable quantity to this country, and greatly resembles Jamaica sarza, for which it is said by Dr. Pereira to be extensively sold, and from which it differs chiefly in yielding a less quantity of extract.

It is manifest that the *S. sarsaparilla* (Linn.), which is a native of the southern states of the American Union, yields none of the article used at present in Europe, though it may yield a portion of what is used in the United States. But this is denied to be used in the United States by Dr. Wood, though indicated in their Pharmacopœia, and Willd., iv., 776 referred to.

Besides the above-described varieties, the produce of different species of smilax, there are numerous spurious or false sarsaparillas, some from known, others from unknown sources. Italian sarza is the root of *Smilax aspera*, the only species native of Europe. It is a very worthless kind, and owes its reputation to a mistake by which it was considered to be the source of the Indian sarza, a truly valuable root, but which is the produce of an asclepiadeous plant, *Hemidesmus indicus*. German sarsaparilla consists of the rhizoma of one or more species of Carex, *C. hirta* and *C. arenaria*. It may easily be distinguished from the genuine by the numerous nodi, which are absent from the smilax.

The active properties are mostly due to the salseparine, the resin, and, when present, to the volatile oil. The more acrid and bitter any specimen of sarza is, the better.

The virtues of sarsaparilla are the subject of much diversity of opinion; many practical men deeming it very useful, while others consider it nearly worthless. This difference seems owing partly to its being employed in different diseases by the one set, from those in which it is used by the other, and still more to inherent differences in the particular root used. It is collected at all seasons of the year, and in all stages of its growth, circumstances which cannot fail to influence its qualities; as young roots gathered before the flower appears must differ greatly from old roots gathered after flowering. But a more important cause of difference exists in the mode of preparing it for administration. The long period enjoined in the 'London and Edinburgh Pharmacopœias' for boiling the root is most injurious, and in reality the order is never obeyed by any of the chemists or druggists who have obtained a reputation for their preparations. They either use water of a temperature far below that of boiling, or perfectly cold water, as ordered by the Dublin Pharmacopœia, and recommended by all the most eminent continental pharmaceutists. The powder is not thus injured, but its bulk and taste are obstacles to its full employment. The compound syrup of the latest edition of the American Pharmacopœia is a most excellent form as an addition to some of the watery preparations. A mixture of preparations made with both hot and cold water seems best, as these menstrua dissolve out different principles. Preparations made *in vacuo* are also commendable, and for keeping long either a hydro-alcoholic compound fluid extract is good, or the same brought to a solid state, which diminishes the bulk, and so fits it for exportation.

The efficacy is sometimes heightened by the introduction of a small quantity of bichloride of mercury—a very objectionable proceeding, as a person taking mercury ignorantly, may expose himself to cold and run extreme risk of life.

The curative powers of sarsaparilla are often very much heightened by combination either with alkalies, especially lime-water, or in other cases with acids, particularly the nitric. When properly prepared, and administered in suitable cases, no one can doubt the efficacy of sarsaparilla. From the high price of it, and the great consumption, attempts have been made in many of the great hospitals to dispense with it or discover a cheaper substitute, but without success. In the worn-out or debilitated systems so common in the patients by whom these establishments are crowded, its utility is daily manifested. This is partly owing to the care taken to procure the best kinds, and partly to the appropriate use made of it, for the sake of economy. It is chiefly used in chronic, syphilitic, rheumatic, gouty, and cutaneous diseases. Its most obvious action is diaphoretic, but if the patient be kept cool, diuretic. In cases where an acid is indicated, the *Hemidesmus indicus*, which is possessed of a natural acid (hemidesmic acid), will be found a useful substitute for the artificial preparations.

If any European plant ever prove a proper substitute for sarsaparilla, it will probably be the *Tamus communis*, or black bryony of our hedges, the root of which, when scraped and applied externally as a poultice, rapidly promotes absorption of effused blood. This is well known to bruisers, gypsies, and others, who to remove ecchymoses of the eye apply a poultice of this root, and generally remove the blackness in twelve or twenty hours. (Tyrrell 'On the Eye,' vol. i., p. 200.)

A long list of plants used as substitutes is given by Th. Martius in his 'Pharmakognosie. In many cutaneous diseases petroleum will be found quite as efficacious. It is far cheaper and taken in smaller doses. Pariglin, or smilacin has been recommended by Palotta, but it has not come into much use.

SMOKE BALLS. [Light Balls.]

SMOKE; SMOKE-PREVENTION. Smoke is the vapour arising from substances in a state of combustion. In its more extended sense the word is applied to all the volatile products of combustion, which consist of gaseous exhalations charged with minute portions of carbonaceous matter, or soot; but the term is frequently employed to express the carbonaceous matter only. It is important to bear this distinction in mind, as it involves a fact which appears to have been sometimes overlooked: namely, that however completely the soot may be destroyed, and the smoke be thereby rendered invisible, it still remains necessary to provide means of free exit for the deleterious gases. The action of an ordinary chimney in conveying the smoke from a fire situated at its lower extremity is very simple. The air in the chimney, being rarefied by the heat, becomes lighter in proportion to its bulk than the surrounding atmosphere, and therefore rises: its place being supplied by fresh air forced in at the lower end by the pressure of the comparatively heavy cold air outside the chimney. A constant rising current is thus created, the force of which is sufficient to carry up with it any light bodies, such as the particles of soot which escape from the fire. The intensity of this current depends much upon the height of the chimney; for it is evident that the higher a chimney is, within reasonable limits, the greater must be the difference between the weight of the column of hot air which it contains, and that of a column of cold air of equal elevation. It is also evident that the hotter the air in the chimney is kept, the more rapidly it will rise. Hence chimneys act better when built in stacks, or when in the interior of a house, than when single, or when outside the walls.

The circumstances which impede the proper action of chimneys, and occasion the annoyance of smoke in houses warmed by common open stoves, have excited the attention of many individuals, and formed the subject of several treatises. Franklin analysed the subject very judiciously, and published a pamphlet pointing out nine causes, or kinds of cause, for the evil. 1. The want of a free supply of air to the bottom of the chimney. It is of little consequence how spacious the room may be into which the chimney opens, if the access of fresh air to the room be cut off. As the hot air escapes from the top of the chimney, its place must be filled by fresh air taken from the room. But if the entrance of the external atmosphere be insufficient, every chimney-full of air abstracted from the room lessens the density of what remains, so that the draught will decrease until the air in the chimney and that in the room are of equal density; after which it will cease altogether, and the smoke will no longer ascend. This inconvenience can only be remedied by providing openings for air commensurate to the demands of the fire. Whenever it is practicable, the best situation for them is near the top of the room, and over the fire-place; because the entering air is then warmed by the warm air which rises to the top of the room, and becomes pretty generally diffused. The object may be attained by leaving a window a little open at the top, or by providing long narrow openings above the window or immediately beneath the cornice. Another plan is the use of a pane of glass in the window, hinged to the frame at its lower edge, and capable of being opened more or less as required; side-pieces of glass being added to prevent the air from entering laterally. Sometimes a number of strips of plate-glass, so arranged as to resemble a Venetian blind, are used; these being so placed as to throw the air upwards. The common ventilator, or *whirligig*, answers the same purpose, and diffuses the air in some degree by its rapid revolution, occasioned by the action of the current upon its inclined vanes. 2. Many chimneys smoke because the opening at the lower end is too large. While a small opening to a tall chimney increases the draught to an improper degree, and causes a wasteful consumption of fuel, a large opening to a short funnel will allow the smoke to escape into the room; because all the air required by the chimney may enter at one side of the opening, leaving the other side free from current, and therefore allowing the smoke to puff out. In such a case the draught is weakened by the coldness of the air which enters the chimney at such a distance from the fire as to be very little affected by it. This defect must be remedied by contracting the opening. 3. A third cause of defective action is the funnel or chimney being too short. The same effect is produced when the flue from an upper story is turned into one from a lower room. The inconvenience of such an arrangement may be somewhat diminished by a contrivance for closing the collateral flue when not in use. The shortness of a chimney may sometimes be rendered harmless by contracting the entrance, so that all the air entering it shall be highly heated, by passing immediately over the fire. 4. Different chimneys in the same house occasionally overpower each other. If we suppose two stoves, each having a distinct chimney, in a room without a sufficient supply of air from without, we may conceive that one fire becoming stronger than the other, may overpower it, and obtain a supply of air down the chimney of weakest draught; the descending current of course blowing the smoke of the weaker flue into the room. Precisely the same effect will take place if the stoves are in different rooms; provided there be, owing to the opening of the doors, a communication between them. This will account for the common case of a parlour chimney smoking whenever the room-door is opened, although it may act properly when the room is closed, and thereby cut off from the effect of the kitchen chimney. The proper cure is clear; if every room have a free supply of air from without, there will cease to be any probability of the chimney of one apartment overpowering that of another. 5. Another cause arises from the situation of the house. If a house stand under the brow of a hill, or in the vicinity of a much higher building, the wind, passing over the higher obstacle, beats down into the chimneys of the sheltered house, and so prevents the exit of smoke. This may sometimes be remedied by raising the chimney, and in other cases by means of a cowl, or turning-cap, the opening of which always turns from the wind. The ordinary cowl is turned by means of a vane attached to its upper part; but one patented by Mr. Pollard is turned by wheels set in motion by the action of the wind upon the oblique vanes of a rotatory flyer. Another contrivance consists of a square box placed on the top of the chimney, each side of which is a door, hinged at one edge, and connected, by means of an iron rod, with the door on the opposite side of the box: in such a way that when one door is closed by the force of the wind, the opposite one opens, and allows the smoke to escape. 6. Chimneys occasionally smoke from a cause just the reverse of that last described. This occurs when the chimneys are low, and stand between the wind and a high building, or neighbouring edifice, so that the air is dammed up, as it were, round about them. Raising the chimneys appears to be almost the only alternative. 7. Another cause of smoking is the injudicious arrangement of the door or doors of a room. If the door be on the same side as the fire-place, and occasion it to smoke by sending a current across the front of the stove, either it must be altered so as to open in the opposite direction, or a screen must be used between it and the stove. 8. Smoke is sometimes blown down a chimney which is out of use. This arises from the circumstance that a stack of chimneys usually maintains a more uniform temperature than the surrounding air. When in the middle of the day, the air generally becomes warmer than that in the chimneys, the current moves *downward*, carrying with it smoke that may happen to be passing over, or escaping from a neighbouring flue. A plate or register, closing the bottom of the chimney when out of use, obviates this inconvenience. 9. Chimneys, which under ordinary circumstances perform very well, occasionally smoke in consequence of the passage of a strong wind over them, which the force of the rising vapour is insufficient to cope with. Among various modes of cure adopted, one is to make the top of the flue funnel-shaped, with a view to facilitate the escape of the smoke under such circumstances; another, to reduce the opening at the top to a long narrow slit. Probably a cowl might be of use in such a case.

The nuisance occasioned by the smoke of coal-fires has formed a subject of complaint from the earliest times in which mineral fuel was extensively used; and the great increase of steam-engine and other furnaces, consequent on the extension of manufactures, has afforded, of late years, additional ground for attempts to abate the nuisance. Such attempts are important, not only for the purification of the air, but also for the economy of fuel; since the matter which gives smoke objectionable density and colour is unconsumed fuel in a finely-divided state. It appears, therefore, that if a supply of air could be thrown into a fire in such a way as to occasion the combustion of the carbonaceous matter, the result would be that a greater amount of heat would be obtained from a given quantity of fuel, at the same time that the nuisance of smoke would be abated. It may be observed, that the quantity of smoke emitted from furnace-chimneys varies much with the state of the fire, being greatest when a mass of fresh fuel is thrown on, and least when the fire has burned clear or the fuel is fully ignited. Attention to this circumstance, on the part of the stoker, will greatly diminish the nuisance; because, if he throw on the fresh fuel in a thin layer, it will the sooner become perfectly ignited; and, by laying it in the fore part of the furnace, the dense smoke arising from it has to pass over that part of the fire which is in a state of more perfect combustion, and is thereby in a great measure consumed. Many of the contrivances introduced or suggested as smoke-consuming furnaces act on these principles; arrangements being adopted to insure the right feeding of the fire without much attention on the part of the firemen.

James Watt was one of the first to obtain a patent for a smoke-consuming or smoke-preventing apparatus. He caused the smoke of the fresh fuel, in its way to the chimney, to pass, together with a current of fresh air, over fuel which had already ceased to smoke, and was intensely hot; by which means the smoke, by coming into close contact with the hot fuel, and being mixed with the current of fresh air, was converted into pure flame, free from smoke. Since that time innumerable plans have been brought forward for introducing the necessary supply of air to the furnace; but while many of them accomplish the purification of the smoke as completely as could be desired, many others increase the consumption of fuel or weaken the draught of the furnace. If the air admitted to the furnace be cold, it diminishes the heat of the fire; and if hot, expense is incurred in heating it, whether this be effected by a separate fire or by passing the air in pipes through the chimney. Most railway companies are required, by their acts of incorporation, to avoid the emission of smoke from their engines; and this is usually done, at great expense, by the use of coke. To lessen this expense, Mr. Chanter devised a plan, consisting in the introduction of a *deflector* dipping into the burning fuel, which compels the smoke from the crude coal to pass through a mass of burning coke, supplied through a small door, and conducted at once to the back of the furnace. By this means three parts of coal may be used to one of coke, with very little risk of much smoke.

Another mode of destroying smoke is by injecting steam into the furnace. The plan has been tried by several inventors, among others by Mr. Iveson. In his apparatus, the steam is thrown into the fire in several minute jets, from a fan-shaped distributor in the fore part of the furnace. The steam not only destroys the smoke, but also greatly increases the intensity of the fire. Thus the necessity for a large chimney is obviated, it being only necessary to provide a small passage for the escape of the gaseous products of combustion. Experiments on the same furnace, with and without the injection of steam, indicate a saving of fuel to the amount of 33 per cent.; the consumption in five hours being respectively 558 and 812 lbs. As a drawback from this saving, the plan requires, in a steam-engine furnace, about one-tenth of the steam generated, and in other furnaces renders necessary the erection of a small boiler. It is proposed, in high-pressure engines, to make use of the waste steam for the purpose of injection.

Besides the numerous plans for the combustion of smoke, various methods have been tried on a limited scale for conducting it to a distance from the buildings in which it is formed, by means of subterraneous channels; and for condensing it by means of a shower of water, so that the sooty matter might be conveyed away by the sewers.

In 1819, a committee of the House of Commons was appointed "to inquire how far it may be practicable to compel persons who use steam-engines and furnaces in their different works to erect them in a manner less prejudicial to public health and comfort." The committee, in their Report, noticed, among other plans, that of Mr. Steel, in which the fuel was supplied in a constant stream, by means of an inclined hopper; the quantity of coal supplied in a given time, and the size of the pieces, being regulated by a grooved roller. The fuel was distributed over the bed of the furnace by the motion of the grate itself, which was of a circular form, and turned on a central pivot. The committee, after much investigation, reported that efficient means for destroying smoke had been "satisfactorily and effectually obtained." An act of parliament was passed to enforce the use of smoke-consuming apparatus; but it was very little attended to, and the smoky condition of our great towns increased quite as rapidly as the increase of population and manufactures. After many years had passed, the Commons appointed another committee of inquiry in 1843. This committee examined a large number of scientific and practical men, among whom were Dr. Faraday, Dr. Arnott, Professor Brande, Dr. Ure, Admiral Parry, Dr. Reid, Mr. Jukes, Mr. Solly, Mr. Muntz, and Mr. Houldsworth. Nearly all concurred in opinion that smoke may be nearly prevented, either by existing methods or by apparatus easy to devise. Voluntary associations had been formed in many large manufacturing towns, including Leeds, Bradford, and Manchester, to put down the nuisance. In numerous factories there was a positive saving of fuel effected by the avoidance of smoke; but most of the manufacturers declared that the apparatus hitherto employed had not fulfilled the promises made. The committee recommended an act of parliament, but none was passed at that time. In 1844, before the Health of Towns Commission, Mr. Thos. Cubitt (than whom few men were more thoroughly versed in the philosophy of house-building) advocated smoke-prevention very energetically, as being practically attainable, morally obligatory, and financially profitable. Another committee sat in 1845, followed by an attempt to pass a smoke-prevention act; but this was frustrated by certain influential manufacturers, who did not like the trouble attending the adoption of new apparatus. When the Health of Towns' Act was passed, clauses were introduced which empowered town-councils to attack the smoke nuisance in their own way, and within the limits of their own towns; and many places availed themselves of this power. After other minor attempts at legislation, acts were passed in 1853, 1856, and 1857, rendering it compulsory to adopt smoke-preventing contrivances. Two of these acts related to the metropolis and one to Scotland. Certain trades were exempted from the operation of the statutes, and certain dates were named on which the penalties for non-observance would begin to be enforced. Not only furnaces employed in trades and manufactures, but also steam-boats working above London Bridge, were brought within the scope of the acts relating to the metropolis. The police received certain powers in relation to this matter, and the provisions of the acts were sought to be enforced by penalties.

Improvements have resulted from these legislative enactments; but the evil is still far from being removed. There seem to be difficulties attending the enforcement of the law. Those manufacturers, whose furnaces are arranged on the old plan, protest against the expense necessary for adapting the smoke-preventing apparatus; and they are not slow to declare that the several inventions fail in some or other of the requisite conditions. On the other hand, the statements are most clear and positive that the evil *can* be prevented, and that a saving in fuel rewards those who resolutely make the attempt. Printers, woollen spinners, builders, metal-founders, button-makers, sugar-refiners, steam corn-millers, porter brewers—all have placed upon record the declaration that gain as well as cleanliness results from the adoption of smoke-preventing apparatus.

We shall make no attempt to describe the numerous forms of apparatus patented within the last few years. All of them belong to one or other of two classes. They attempt either smoke-*consumption*, by supplying the heated smoke, at a particular spot, with fresh air enough to kindle and consume it; or smoke-*prevention*, by so supplying fuel that it may ignite without forming smoke at all. Jukes' apparatus belongs to the latter class.

The inventions of Dr. Arnott would call for some attention here, were it not for the fact that his ingenious stoves and ventilating apparatus had better be described under WARMING AND VENTILATION, in connection with many other kinds of apparatus for similar purposes.

SMUGGLING is the clandestine introduction of prohibited goods, or the illicit introduction of goods by the evasion of the legal duties. Excessive duties present an overwhelming temptation to men to evade them; and the law loses a great part of its moral influence when it first tempts to violation of it and then punishes the offence. The true remedy is a wise tariff. It annihilates at once a traffic which no ingenuity can ever put down; for all experience proves that so long as a profit can be made by smuggling sufficiently high to counterbalance the necessary risk, it will not fail to flourish. The decrees of Berlin and Milan, instead of annihilating commerce, only forced it into extraordinary channels. Silk from Italy, for example, instead of being received in England by the most direct means, often arrived by way of Archangel and Smyrna; in the former instance being two years, and in the latter twelve months, on its passage. Sugar, coffee, tobacco, and cotton-twist were despatched from England to Salonica, and thence conveyed by horses and mules through Servia and Hungary to Vienna, from which place they were distributed over the Continent, in defiance of the rigorous decrees of Napoleon; it might happen that coffee was consumed at Calais which, instead of being sent direct from London, arrived by the above circuitous route.

We have only to examine the tariff of any country to know if smuggling is practised; and if a bad system of commercial policy has been long pursued, there the smuggler will be found. The *contrabandista* of Spain figures in novels and tales of adventure. In no country is the illicit trade so general and extensive. The exports to Gibraltar from England are very large, and a great proportion is introduced by smugglers into the interior. Nearly the whole of the tobacco imported into Gibraltar is smuggled into Spain, where the article is one of the royal monopolies. On the French frontier the illicit trade is equally active.

The vicinity of France and England, and the injudicious character of their respective tariffs, long encouraged smuggling to a large extent on both sides of the Channel.

The reduction of the duties on silks, tea, spirits, wines, and numerous other articles, has done more to repress smuggling than all the efforts of the revenue officers aided by a large armed force.

The present acts relating to smuggling are 3 & 4 Wm. IV. c. 53, and 4 & 5 Wm. IV. c. 13.

SNOW. It has been stated [RAIN, vol. vi. col. 925] that rain, snow, and hail are formed by the precipitation of vapour when two volumes of air of different temperatures, and saturated with moisture, become mixed together; the nature of the precipitation depending on the resultant temperature and on that of the region of the atmosphere through which the aqueous particles descend towards the ground. Now when the precipitating water is frozen into crystals of ice, united together in such a manner as to reflect light to the eye in great abundance from all, thus producing a sensation of whiteness, the assemblages of crystals constitute snow. In all probability it is formed by the immediate freezing of aqueous vapour, without the sensible intervention of the liquid state. Proximity to the earth's surface is not required for its production; Mr. Green, the aeronaut, met with a severe snow-storm at the height of a mile and a quarter. The formation of snow through a considerable tract of the atmosphere appears at a distance as a bluish, sometimes indigo-blue, haze.

M. Monge observes ('Annales de Chimie,' vol. v., p. 1), that the crystallisation of sal-ammoniac presents phenomena similar to those which are observed in the formation of snow. If a saturated solution of sal-ammoniac in a warm state be allowed to cool in a tranquil air, the surface of the liquid is that which first arrives at a state of supersaturation, and there the first crystals are formed; these sink immediately, and in descending they unite with similar crystals formed in the liquid itself, so that they arrive at the bottom of the vessel in white flakes.

The flakes of snow usually consist of brilliant spicular icicles, which diverge from a centre in six directions, and resemble stars having so many rays, upon each of which small crystals are sometimes formed; but if the atmosphere is agitated, the original flakes strike against each other, and uniting in groups by regelation [ICE], in consequence of small quantities of moisture adhering to them, they descend in irregular forms. In regions of the earth far to the north or south, the air, when allowed to enter through a small aperture into a heated apartment, has frequently caused the warm vapour to be converted into snow. ('Bibliothèque Universelle,' 1830.)

Beccaria observed that his apparatus for ascertaining the electrical state of the atmosphere indicated the presence of electricity in snow as well as in rain; and, according to the observations of Schübler, it is more commonly positive than negative. The lightness of the flakes, by which they float about in the air when agitated, is the result of their surface being great when compared with their volume. The sp. gr. of snow has been stated to be very variable; and according to Musschenbroek, that of some, of the stelliform kind, was only $\frac{1}{24}$ of the specific gravity of water, but this must have been the specific gravity of the mass, a mixture in fact of air and ice; and M. Quetelet has since found that the greatest density is nearly $\frac{1}{2\cdot8}$ of that of water, the temperature being 34·5° (Fahr.). He ascertained also that the density of fine snow having no determinate form was about $\frac{1}{4}$, the temperature being 32°, and that the least density varied from $\frac{1}{10}$ to $\frac{1}{12}$ of that of water, at which time the snow had the form of small stars, and the temperature varied from 29·7° to 18·5°. It is, however, difficult to understand these results; it would appear that they also must relate to an aggregate of snow and air, as there is no reason why the specific gravity of crystals of snow should differ greatly from that of ice, which is always crystalline, and has the sp. gr. 0·918.

Snow has been observed to fall in a fine powder, not having any appearance of regular crystals, and sometimes in grains, as fine as those of what is called basket salt.

The flakes have, even in temperate regions, many varieties of form, and are often very elegant; but the polar regions of the earth are those in which it has been supposed that nature has displayed her power in creating this species of beauty in the highest degree and to the greatest extent. In the 'Phil. Trans.,' 1775, may be seen numerous delineations of the figures assumed by flakes of snow as they were observed by Dr. Nettis, of Middelburg in 1740; but the late Rev. Dr. Scoresby, in his 'Account of the Arctic Regions,' has given still greater varieties; the latter gentleman, besides dividing them into classes, has also expressed their magnitudes, and the state of the barometer and thermometer when the snow fell.

Of these classes the first is called "lamellar," and is divided into many different species: one of the latter is a thin transparent hexagonal plate, or a hexagonal plate with white lines parallel to the sides of the polygon, and sometimes there is a starlike figure in the centre; the magnitudes vary, and the greatest is about $\frac{1}{10}$ inch diameter. Another species, and this is the most ordinary appearance of snow, is the stelliform; the figures 1, 2, and 3 represent some of the most remarkable varieties of this kind; its magnitude varies, but the diameter of the greatest is about $\frac{1}{3}$ inch, and it occurs most abundantly when the temperature of the air is near the freezing point of water. Sometimes the stars appear to have twelve points, but Dr. Scoresby thinks that these are formed merely of two stellar plates applied one on the other The six following figures represent assemblages of hexagonal crystals the diameters of the first two kinds are respectively $\frac{1}{10}$ and $\frac{1}{20}$ inch and those of the rest are $\frac{1}{3}$ inch diameter; they are usually formed at temperatures between 32° and 20° (Fahr.).

The second class is also lamellar, but it differs from the former in having a spherical nucleus, either transparent or white, about $\frac{1}{4}$ inch diameter; and sometimes spicular radii proceed from thence in different directions at angles of 60° with each other. The temperature at which this class is formed varies also from the freezing-point to 20° (Fahr.).

The third class consists of spiculæ or six-sided prisms; of these, the finer sort, which are formed at the temperature of 28°, resemble white hairs very delicate and clear, and about $\frac{1}{4}$ inch long; the coarser kinds are formed in the lower region of the atmosphere, at about the freezing temperature.

The fourth class is of a pyramidal form and about $\frac{1}{30}$ inch high, but Dr. Scoresby could not determine whether the base was triangular or hexagonal. The fifth class consists of hexagonal crystals united together by a slender spicular crystal, so as to resemble two wheels with an axle. Both of these kinds are very rare. Dr. Scoresby saw the latter only twice and the former only once.

M. Huber Burnand, speaking of the character of the snow which fell at Yverdun in 1829 and 1830, states that it was crystallised in stellar plates with six rays, along each of which were disposed filaments arranged like feathers, and these again supported finer filaments similarly arranged; the plates, which were extremely thin, were perfectly plane and regular. ('Bibl. Univ.,' 1830.) It is also related in the same work, that in 1829 the frost at Yverdun assumed every day a different form, being sometimes disposed in parallel groups or fillets; sometimes it resembled leaves, and occasionally spines about an inch long, which were terminated by a flat rosette with six divisions.

The severe weather experienced in the vicinity of London, and over the south-west and eastern parts of England at the beginning of the year 1855, of which no parallel had taken place since that of 1814, which it greatly resembled, as well for depression of temperature as for the duration of the frost, was remarkable also for the peculiar character and continuous fall of snow, which first made its appearance on January 16th, and lay on the ground till after the end of February. We are indebted to Mr. Glaisher, the Secretary of the British Meteorological Society, for a particular account of this snow and its crystals, which is annexed to the Report of the Society read at the fifth annual meeting, May 22, 1855. Much of this snow, Mr. Glaisher observes, was "of that peculiar character which former writers designated Polar Snow, it having been chiefly composed of crystalline particles, which they supposed to be confined, with rare exceptions, to the Arctic regions. This supposition, however, is not supported by the recent prevalence of innumerable crystals, that have exhibited a degree of crystalline formation equal to any that has been recorded in colder latitudes. . . . . . The primary figure or base of each crystal I determined to be a star of six radii, or a hexagon of laminæ, and the compound varieties to include combinations of spiculæ, prisms, cubes, and rhomboids, aggregated upon and around the central figure, according to the degree of its complexity." The paper is illustrated by 88 small and 63 greatly enlarged figures of the snow crystals, the joint productions of the pencils of Mr. and Mrs. Glaisher, and probably the most valuable series of such representations extant. The figures above, copied from Dr. Scoresby, 6, 7, and 8, it will be observed, have an inner tracing of the hexagon. Similar crystals to these were observed by Mr. Glaisher, who had not seen them previously, nor any figures of them, except those of Dr. Scoresby of those seen by him in the Arctic Seas. But the forms of snow-crystals are doubtless dependent on the temperature of the air and the amount and distribution of the aqueous vapour it contains, the differences in those respects of the different strata of air, the interchange of currents, and other physical circumstances, and not otherwise upon difference of locality than as that may involve a difference in those circumstances. The forms ordinarily characteristic of the snow of one latitude or region may be produced in any other, wherever snow can occur. It does appear, however, that the most regular and complex stellate aggregations accompany the lowest temperatures. The extraordinary complexity of many of these crystals of snow, when considered in connection with the principle of regelation which governs the union of separate portions of ice, leads to the suspicion that infinitesimally small crystals result from the solidification of vapour, which undergo accretion and are subsequently incorporated with each other by regelation, in directions accordant with those of the crystalline forces to which the elementary forms are due. The crystallography, however, of solid water, or ice, which of course is that of snow, is at present in a condition of singular contradiction. We appear not to know with certainty to what system of crystallisation it should be referred, or even whether it does not belong to more than one system; though there is strong evidence that it must belong, in part at least, to the rhombohedral system, to which it has usually been referred. The facts known respecting it will be stated with the other properties of ice, in the article WATER.

Snow, in the form of cylinders and spheres or spheroids, has been occasionally observed in North America. The former were produced by the snow deposited in a second shower upon some which had previously fallen, and the surface of which had been covered by a thin coating of ice. A violent wind then caused the particles of snow to roll on the ice, and the masses thus produced assumed perfectly cylindrical forms of various sizes, the greatest being 2½ or 3 feet diameter; they were hollow at each end. The spherical balls were from 1 inch to 15 inches in diameter, and were also formed chiefly by rolling, though some were found in enclosures where they could not have rolled, and, therefore, they are supposed to have been formed in the atmosphere itself; they were very light, and were composed of crystals irregularly united. (Silliman's 'Journal,' vols. ii. and vi.) Similar balls were observed in East Lothian, in 1830, by Mr. Sheriff; and this gentleman relates that they were composed only of snow, for one of them being cut through was found to have no hard body for its nucleus. ('Edin. Phil. Journal,' ii. 58.) Mr. Luke Howard records an instance, in which, with the surface at 33° or 34°, and during a strong wind, the snow, instead of driving loose before the wind, was collected occasionally into a ball, which rolled on, increasing till its weight stopped it: thousands of such balls were seen lying in the fields, some of them several inches in diameter. The balls of snow, torrents of which constitute what are called rolling avalanches [AVALANCHES], appear to be formed in a similar manner, though by means chiefly mechanical, in addition to regelation, which must have place in all these accretions.

When an extensive tract of country is covered with newly-fallen snow, its glare has a painful and injurious effect on the eyes, from which the traveller has to guard them by a crape veil, the natives using various similar means of protection. It is, however, from such snow alone that much inconvenience is felt, indicating, probably, that it is owing to the light reflected from the myriads of facets which the crystals of snow present. Dr. Joseph D. Hooker remarks, that he has never suffered inconvenience from this cause in crossing beds of old snow, or glaciers with weathered surfaces, which absorb a great deal of light, and reflect comparatively little, and that little coloured green or blue. The changes to which snow is subject after descending to the ground, according to the circumstances of temperature, weather, exposure, and the nature of the surface upon which it has fallen, are evaporation, liquefaction, and conversion into a compact ice. It evaporates at all temperatures. Mr. Howard found a circular area, of five inches diameter, to lose 150 grains troy from sunset to sunrise, and about 50 grains more by the following sunset, the temperature varying from 18° to 30°. This evaporation probably supplies the vapour which appears in the form of mist after a snow-fall, and also that which is condensed again in the form of a secondary fall of snow.

The process of conversion of snow into glacier ice has been noticed in the article GLACIERS, in NAT. HIST. DIV. A similar conversion, in localities of a different character, has been observed by Dr. Hooker, who describes the beds of perennial snow in the Sikkim Himalaya, which extend below the true inferior limit of perpetual snow (see the following article), as having great resemblance to glaciers, from which, indeed, he considers them undistinguishable. Though broad and convex, and occupying mountain slopes,—not filling hollows like glaciers commonly so called,—they display the ribboned structure of glacier-ice, and descend at a rate and to a distance depending on the slope and on the amount of annual accumulation behind. [CLOUD; HAIL.]

SNOW, PERENNIAL, or PERPETUAL. In the article CLIMATE (col. 968–70), a general view of this subject has been given, together with particulars of the elevation of the snow-line under different latitudes and in different localities, both as indicated by theory and shown by observation. We are now enabled to enter in a more precise manner into the consideration of the varying circumstances which govern the position of the snow-line, and also into the special history of perpetual snow as it exists about and upon the greatest and highest mountains of the globe. For the materials of these we are chiefly indebted to Dr. Joseph D. Hooker, who, in the Appendix to his 'Himalayan Journals,' has treated the subject with views at once more general and more philosophical, perhaps, than have been applied to it since the original investigations of Wahlenberg, Von Buch, and Humboldt; and has largely illustrated them by the facts of the distribution of snow in Nepaul, Tibet, and the Himalaya, which are stated in their appropriate places in his 'Journals' themselves.

It must be premised that three things are frequently confounded together in popular science and in books of travels. First, the elevation in the atmosphere, or above the general surface of the earth, as defined by the level of the sea, of the temperature of 32° Fahr., or the freezing point, for each latitude, as affected by the distribution of land and sea, from which, in union with the solar temperature, results the temperature of each isothermal line at the surface.

Secondly, the position of the inferior limit of the beds of perpetual snow—the actual snow-line in this sense—on mountainous elevations, as dependent on the cause just assigned, in conjunction with local causes on the great scale, and as existing in fact at that particular elevation for each region, below which all the snow that falls melts. This may be considerably below or considerably above the line of 32°.

Thirdly, the altitude at which much snow is *perennial*, in the ordinary sense of the word—its permanence arising from local and from temporary (though recurrent) meteorological causes—masking, by its extension downwards, the true limit of perpetual snow as defined above. It is requisite, however, for the due apprehension of the subject, that the distinction between these three things should be carefully preserved in the mind.

Dr. Hooker has stated his belief ('Him. Journ.,' vol. ii., p. 394), "that the limit of perpetual snow is laid down too low in all mountain regions, and that accumulations in hollows, and the descent of glacial ice, mask the phenomenon more effectually than is generally allowed." He defines the limit, "in general terms only, as being that where the accumulations are very great, and whence they are continuous upwards, on gentle slopes. All perpetual snow, however," he continues, "becomes ice, and, as such, obeys the laws of glacial motion . . . . .; whence it follows, that the lower edge of a snow-bed placed on a slope is, in one sense, the termination of a glacier, and indicates a position below that where all the snow that falls melts. . . . It is impossible to define the limit required with any approach to accuracy. Steep and broken surfaces, with favourable exposures to the sun or moist winds, are bare much above places where snow lies throughout the year; but the occurrence of a gentle slope, free of snow, and covered with plants, cannot but indicate a point below that of perpetual snow." A careful examination of those great beds of snow in the Alps, from whose position the mean lower level of perpetual snow, in that latitude, has been deduced, convinced Dr. Hooker that they are winter accumulations—of the kind alluded to above, due mainly to eddies of wind—of far more snow than can be melted in the following summer, being hence perennial in the ordinary sense of the word only. It follows that the true limit of perpetual snow is much higher in the Alps than it is usually supposed to be. He proceeds to show that the altitude of the limit in the Alps has been stated by Professor James Forbes more than 1000 feet in defect, the Jardin, on the Mer de Glace, at the elevation of 9500 feet, being evidently below the limit, to which, however, Professor Forbes had assigned the elevation of 8500 feet only.

Proceeding to the principal scene of Dr. Hooker's own researches, we find that there are two secondary considerations which materially affect the melting of snow, and therefore exert a material influence on the elevation of the snow-line, but which have not been sufficiently dwelt upon, though they bear directly upon the great altitude of that line in the most elevated regions. From the imperfect transmission of the heating rays of the sun through films of water, it follows that the direct effects of the rays, in clear sunshine, are very different at equal elevations of the moist outer and dry inner ranges of the Himalaya. Secondly, naked rock and soil absorb much more heat than surfaces covered with vegetation, and this heat, radiated from them again, is much more rapidly absorbed by the white snow than the direct heat of the sun's rays is. Hence, at equal elevations, the ground heats sooner, and the snow is more exposed to the heat thus radiated in arid Tibet than in the wooded and grassed mountains of Sikkim. In the latter region, "the position and elevation of the perpetual snow vary with those of the individual ranges, and their exposure to the south wind. The expression that the perpetual snow lies lower and deeper on the southern slopes of the Himalayan mountains than on the northern conveys a false impression. It is better to say that the snow lies deeper on the southern faces of the individual mountains and spurs that form the snowy Himalaya. The axis itself of the chain is generally far north of the position of the spurs that catch all the snow, and has comparatively little snow on it, most of what there is lying upon north exposures." Thus appears to be at last explained the apparent anomaly that the snow-line ascends in advancing north to the coldest Himalayan region; the position of the greatest peaks and of the greatest mass of perpetual snow being generally assumed, though erroneously, as indicating a ridge and watershed. "Travellers arguing from single mountains alone, on the meridional ridges, have at one time supported and at another denied the assertion, that the snow lies longer and deeper on the north than on the south slope of the Himalayan ridge."

The enormous accumulation of snow in Sikkim at 15,000 feet exercises a decided influence on the vegetation, preventing its extension upwards, which, in other situations, takes place to 16,000 and 17,000 feet. Glaciers descend to 15,000 feet in the tortuous gorges which immediately debouch from the snows of Kinchinjunga, but no plants grow on the *débris* they carry down, nor is there any sward of grass or herbage at their base, the atmosphere immediately around being chilled by the snows, and the summer sun rarely warming the soil. In the vicinity of Kinchinjhow, 21,000 feet high, and where the mean level of perpetual snow is 19,000 feet, coinciding, probably, with a mean temperature of 20°, the glaciers do not descend below 16,000 feet, but a green sward of vegetation creeps up to their bases, and herbs grow on the patches of earth they carry down, while dwarf rhododendrons cover the moraines. Dr. Hooker concludes on this subject with the following general statement :—"Looking eastward or westward on the map of India, we perceive that the phenomenon of perpetual snow is regulated by the same laws. From the longitude of Upper Assam in 95° E. to that of Kashmir in 75° E., the lowest limit of perpetual snow is 15,500 to 16,000 feet, and a shrubby vegetation affects the most humid localities near it, at 12,000 to 14,000 feet. Receding from the plains of India and penetrating the mountains, the climate becomes drier, the snow-line rises, and vegetation diminishes, whether the elevation of the land increases or decreases; plants reaching 17,000 and 18,000 feet, and the snow-line 20,000 feet. To mention extreme cases : the snow-level of Sikkim in latitude 27° 30′ is at 16,000 feet, whereas in latitude 35° 30′ Dr. Thomson found the snow-line 20,000 feet on the mountains near the Karakoram pass, and vegetation up to 18,500 feet—features I found to be common also to Sikkim in latitude 28°."

The progress of physical geology brings before us, from time to time, the conditions of the earth's surface at former periods. An example of this, probably involving the consideration of the great extension of snow and ice in the northern hemisphere, southward from the arctic regions, at what has been termed the glacial epoch, as alluded to in several former articles, is stated by Dr. Hooker nearly in the following terms :—Were the snow-level in the Dingcham province of Tibet as low as it is in Sikkim, or 15,000 feet, the whole of Tibet, from the Donkia mountain northwards to the Yaru-Tsampu river, the average direction of which is west and east nearly in the latitude of 29° 10′, "would be everywhere intersected by glaciers and other impassable barriers of snow and ice, for a breadth of fifty miles, and the country would have no parallel for amount of snow beyond the Polar circles. It is impossible to conjecture what would have been the effects on the climate of northern India and central Asia under these conditions. When, however, we reflect upon the evidences of glacial phenomena that abound in all the Himalayan valleys at and above 9000 feet elevation, it is difficult to avoid the conclusion that such a state of things once existed, and that at a comparatively very recent period." Valuable information on this subject, as well as on the philosophy of the snow-line as at present existing, will be found in Mr. W. Hopkins's paper, "On the causes of changes of climate," 'Quart. Journ. of Geo. Soc.,' vol. viii., p. 76-87.

SNOW, RED. [See Nat. Hist. Div.]

SNUFF. [Tobacco.]

SOAP MANUFACTURE. Soap originally meant the compounds derived from the union between fatty bodies and the alkalies potash and soda. Although the name is still usually thus limited in its meaning, it has nevertheless been extended to compounds of oleaginous bodies with some earthy and metallic bodies, having but few properties in common with soap properly so called.

Properties.—It has been found by Chevreuil that different varieties of fatty matter consist chiefly of two kinds: one hard, to which he gave the name of *stearin*; and the other soft, which he termed *olein*. He also discovered that stearin is composed of stearic acid and a peculiar principle which, on account of its sweet taste, he named *glycerin*; and it was further proved by his experiments that olein consists of oleic acid and glycerin. Stearin is therefore a stearate of glycerin, and olein an oleate of the same substance. When, in the manufacture of soap, an alkali (soda, for example) is heated with tallow, the soda gradually dislodges the glycerin from combination with the stearic and oleic acids, and by combining with them, forms soap, or, in other words, a compound of stearate and oleate of soda, and the glycerin remains in solution.

In vegetable fat oils—olive-oil, for example—the glycerin is combined with margaric and oleic acids, forming margarate and oleate of glycerin; and, consequently, soap made with this oil is a margarate and oleate of soda, instead of a stearate and oleate of this base.

The soaps which have the alkalies for their bases are soluble in water, though the solution is in general milky; they are also soluble in alcohol, and the solution is used frequently as a test of what is called the *hardness* of water. [Soap-Test.] Acids also decompose soaps, and though the effect is apparently similar, yet it is in reality different: thus when sulphuric acid is added to soap, a white precipitate is formed, but this is merely the fatty acid which the soap contained, and shows the change which the fat employed has undergone; it is either stearic, oleic, or margaric acid, &c., or a mixture of two or more of them. Sulphate of soda remains in solution when a soda soap has been thus decomposed. There are certain preparations used in medicine under the names of emulsions and liniments, which are obtained by merely agitating either ammonia, potash, soda, or lime-water, with oil. The first of these is an ammoniacal soap; the second and third are imperfect alkaline soaps; and the fourth is an earthy soap to which barytes and strontia-water form compounds nearly analogous; these earthy soaps are insoluble in water, or nearly so. Metallic soaps are formed by heating certain metallic oxides, as those of lead, mercury, and bismuth, with fatty matter; glycerin is separated, as has already been mentioned, and the metallic soaps formed are insoluble in water. The only soap of this kind extensively employed is that of oxide of lead, which is largely used under the name of diachylon, or lead plaster.

Manufacture.—Some of the soap-factories of the present day carry on operations with the aid of considerable chemical and mechanical skill. There is, however, not much that requires description here.

Mottled soap, a kind much used in England, is made of tallow, kitchen stuff, soda, water, and a little salt. The tallow principally employed is brought from Russia, and arrives in a solid state in barrels; it is tolerably pure, and is ready for use at once. The impure grease known as kitchen-stuff requires much heating, straining, and purifying before it is fitted for use; and even then it is not employed for the better soaps. The alkali formerly used, as has already been stated, was obtained from kelp and barilla; but the carbonate of soda obtained from common salt is now almost exclusively used. The soda being required almost in a caustic state, the carbonic acid is driven off for the soap-maker's purposes. The caustic soda is dissolved in water to form a *ley* or *lye*. The ley is pumped into boilers, and mixed with the fatty substances. Steam-heat is applied, and the mixture is boiled until the fat has combined with all the alkali of the ley. The spent ley is pumped up, fresh ley is introduced, and the boiling proceeds. This is repeated several times, a stronger ley being used each time than before. When the soap is nearly finished, the "mottling" is given by sprinkling a small quantity of very dense ley; this percolates slowly through the mass, leaving dark-coloured veins in its track. When the soap is finished, it is laded into buckets, and thence transferred to *frames*. These frames are upright oblong boxes, made either of wood or iron, and easily taken to pieces. The soap, when the frames are full, is allowed to cool and solidify. Each frame being taken to pieces, the mass of soap, sometimes weighing as much as three or four thousand pounds, is exposed to view. It is cut up into slabs or layers by a wire being drawn through it, following the marks of certain gauge-lines. The application of a similar wire in a different way afterwards separates the slabs into bars about 15 inches long, 3 inches wide, and 3 inches deep.

Curd or *white* soap is made nearly in the same way as mottled, but with a more careful selection of ingredients, and a better management of some of the processes.

Yellow soap is distinguished from the others by the large amount of resin and palm-oil contained in it. The casks of palm-oil, as brought from Africa, are placed over a trough with the bung-hole downwards; the steam-pipe is admitted, and the melted substance flows out. The oil is bleached by a chemical process, and then the soap-making proceeds as before. The resin and the palm-oil both serve the purpose of tallow, and are the cause of the relative cheapness of yellow soap.

Soft soap, used principally in the woollen manufacture, is made chiefly of oil and potash. The oil may be whale, seal, olive, linseed, or any that comes most readily to hand, and is combined with a little tallow to increase the stiffness. Soft soap is not shaped in frames, but is poured at once into barrels or casks.

Fancy soaps, as they are called, such as are sold by perfumers, are generally made from good white soap, remelted, and modified by the addition of perfumes, &c.

Dr. Normandy in 1841 patented an invention for using up all kinds of gums and resins in soap by the addition of sulphate of soda. He made hard soap cheap by that means; but his operations were checked by the Excise insisting on the same rate of duty as was paid for the high-priced soaps. His patent, not having been a profitable one, was renewed in 1855 for three years.

A substance called *soap bark* was brought to Europe from some tropical country in 1859. It is black without, and yellowish white within, very heavy and dense. When the white layers are macerated in water, they produce an emulsion which, when mixed with oil, may be used as soap.

Soap Trade.—The soap manufacture is one of considerable importance. The principal seats in England are Liverpool and Runcorn, London, Brentford, Bristol, and Hull. Nearly three-fourths of the total quantities of soap are made at these places; but there are also manufactories of considerable extent at Bromsgrove, Newcastle, Gateshead, Warrington, and Plymouth. In Scotland, two-thirds of the total quantity of soap are made at Glasgow and Leith.

In 1711 an Excise duty of 1*d.* per lb. was first imposed on all soap made in Great Britain, which was raised in 1713 to 1½*d.* per lb. In 1782 the duty was again increased, and a distinction was, for the first time, made between hard and soft soap, the duty on the former being 2½*d.*, and on the latter 1¾*d.* per lb. In 1816 hard soap was subjected to a duty of 3*d.* per lb. In 1833, the duty was 1½*d.* per lb. on hard soap, and 1*d.* per lb. on soft. The interference of the Excise in the manufacture of soap was, until recently, exceedingly arbitrary and vexatious; but in the 'Seventeenth Report of the Commissioners of Excise Inquiry,' 1835, the discontinuance of the system of survey which then existed was recommended. The act 3 and 4 Vict. c. 49, passed in 1840, repealed seventeen other acts, so far as they concerned the making of soap. The article may now be made in any way or of any material which the manufacturer thinks most judicious, as the Excise does not interfere with the process of manufacture.

When the duty on hard soap was 3*d.* per lb., the selling price averaged about 6*d.*, out of which another ½*d.* was absorbed in duties on the tallow and other substances used in the manufacture. The 3*d.* duty, as has been stated, was reduced to 1½*d.* in 1833; and in 1853 the duty was wholly repealed. In 1852, the last year for which official returns are obtainable, rather more than 200,000,000 lbs. of soap were made in the United Kingdom; of which the largest items were—London and vicinity, 54,000,000 lbs.; Liverpool and vicinity, 47,000,000 lbs.; Glasgow and vicinity, 16,000,000 lbs. The export of soap is not large; for the three years, 1858, 1859, 1860, it varied from 160,000 lbs. to 190,000 lbs.

The increasing use of palm oil is perhaps the chief commercial novelty in the soap manufacture.

SOAP, *Medical Uses of.* In pharmacy and medicine the term soap is applied to combinations not only of oily and fatty matters with the alkalies soda or potash, but also with the volatile alkali (ammonia), lime (an alkaline earth), and metallic oxides, especially oxide of lead; likewise to solutions of resins in liquid potash, such as guaiacin [GUAIACUM], called therefore *Sapo guaiacinus.* The combinations of oils with ammonia or lime, being very thin, are generally termed *liniments;* the common one of hartshorn with oil is an example of the former, while oil and lime-water constitute the common application to burns termed Carron oil, from its frequent employment in the great iron-works at that place. The combination of oil with oxide of lead is generally termed a *plaster.* Some combinations of a volatile or fixed oil with an acid are sometimes called soaps, such as that of oil of turpentine with hydrochloric acid (artificial camphor), or of almond oil with sulphuric acid (*Sapo acidus*): but these are scarcely entitled to be so regarded. Among continental pharmaceutists, many cerates and mixtures of metallic salts with common soap are termed *soaps,* but they are more correctly called plasters.

Of hard soaps, the fine kinds are made with soda and the purer vegetable oils, and the inferior kinds with animal oils or the coarser vegetable oils or resins. White soda soap is prepared with caustic soda and olive oil (in Spain) or with almond oil (in France). In its purest state it is called *medicinal* soap; in a less pure state, it is called Alicant, Venice, or Spanish soap. The Castile or marbled soap has this appearance communicated to it by sulphate of iron and red oxide of iron being added and stirred through it when the soap is nearly made. These are impurities which render it less fit for medical use in many cases than the white soap. When properly prepared, white soap should neither make an oily mark on paper nor have a burning alkaline taste. It should be perfectly soluble in pure water and in alcohol. [SOAP-TEST.] When an alcoholic solution is evaporated, the residuum constitutes *transparent* soap.

White soda soap is the only one which should be used internally. It is chiefly employed to form pills, which are gently aperient and antacid; their power in this latter respect is greatly increased by the addition of exsiccated carbonate of soda: this combination is of great utility in the treatment of gouty and calculous disorders, when an alkali is indicated. In other cases it is used to prevent the pills becoming hard and insoluble; such as compound rhubarb pills. White soap furnishes a ready antidote to the strong mineral acids, in cases of poisoning by any of these.

Soft soap is directed by the London Pharmacopœia to be made with potash and olive oil only, but this order is seldom complied with. The soft soap, in which both soda and potash are used, is made with olive and other oils and tallow. It is employed only to form the compound sulphur ointment. Soft soap is of great service in many cutaneous diseases, several of which, when in a mild form, may be cured by it alone. It may be rendered still more useful by the addition of sulphur or sulphuret of potash (liver of sulphur). In the treatment of scabies, porrigo (ring-worm), and such diseases, this application is far superior to the ointments and other greasy compounds commonly employed, which increase the filth or uncleanness by which the disease is aggravated. It is also much cheaper. Many other soaps are vended, pretending to special qualities, such as glycerine soap, tar soap, &c. Soap formed of cocoa-nut oil has the great advantage of being soluble in salt water, and so can be used at sea.

SOAP-TEST. A solution of white curd soap in proof spirit; it is used in ascertaining the amount of hardness of waters.

The action of hard water upon soap has already been alluded to. [CALCIUM, *carbonate of lime.*] By using a solution of soap of known strength, and adding it to a given quantity of hard water until no more of the familiar curdy precipitate is thrown down, the amount of hardness will obviously be at once indicated. The method of preparing and applying this soap test is as follows:—

Sixteen grains of pure carbonate of lime are dissolved in pure hydrochloric acid, the solution evaporated to dryness on a water bath, the residue re-dissolved in water, again evaporated to dryness to ensure the absence of free acid, and the residue now dissolved in one gallon of distilled water. The resulting liquid is a solution of hydrochlorate of lime, or, more correctly, chloride of calcium, but the amount of lime in it is identical with that in the sixteen grains of carbonate of lime, and inasmuch as all soluble lime salts act similarly upon soap, that is, without any influence of the acid contained in them, it follows that the gallon of chloride of calcium solution accurately represents a natural water whose hardness is due to sixteen grains of carbonate of lime in a gallon. All that is now necessary is to ascertain how much of a dilute alcoholic solution of soap must be added to a given quantity of the chloride of calcium solution before a permanent lather is produced. This being done the soap-test has henceforth a value given to it, inasmuch as if it be added to any hard water, equal in volume to that of the artificial hard water previously experimented with, until a permanent lather be produced, the amount so added indicates the number of grains of carbonate of lime present in the gallon. The quantity of water tested is usually and conveniently one thousand grains, and the soap-test is used to greatest advantage when poured from a burette divided by transverse markings into measures each containing ten grains: the soap-test should, moreover, be so diluted by its proof-spirit solvent, that thirty-two measures require to be added to one thousand grains of the artificially prepared standard solution of sixteen degrees of hardness before complete precipitation of the lime is produced and a permanent lather formed.

In applying the soap-test to a normal water, the specimen of the latter should be placed in a bottle of five or six ounces' capacity. The solution of soap must then be added in small portions at a time and the mixture well shaken in the intervals. When indications of a lather appear on the surface of the liquid, the additions of soap-test must be very small, and finally when a lather is produced that does not subside until after the bottle has remained undisturbed on its side for three minutes, the amount of soap-test added is noted; an inspection of a table similar to the one here appended at once indicates the degree of hardness per gallon.

CLARK'S SOAP TEST-TABLE FOR HARDNESS OF WATER.

Degree of Hardness.	Measures of Soap Test.	Difference for next Degree of Hardness.
0. (Distilled water)	1·4	1·8
1. ,,	3·2	2·2
2. ,,	5·4	2·2
3. ,,	7·6	2·0
4. ,,	9·6	2·0
5. ,,	11·6	2·0
6. ,,	13·6	2·0
7. ,,	15·6	1·9
8. ,,	17·5	1·9
9. ,,	19·4	1·9
10. ,,	21·3	1·8
11. ,,	23·1	1·8
12. ,,	24·9	1·8
13. ,,	26·7	1·8
14. ,,	28·5	1·8
15. ,,	30·3	1·7
16. ,,	32·0	

Excess of carbonic acid in a water is apt to decompose a lather once formed and an experiment may be thus interfered with. To avoid this source of error Professor Clark, who is the author of the process now described, recommends that the water be violently agitated before the addition of the soap-test, the superstratum of air being two or three times renewed by suction through a glass tube. When a water is of more than sixteen degrees of hardness it should be diluted with its own bulk of distilled water before proceeding with the addition of soap-test.

Salts other than carbonate of lime confer hardness upon water, moreover an equal number of degrees of hardness is produced by very different amounts of the several salts. Thus, to produce ten degrees of hardness the annexed quantities of the following salts are necessary:—

Carbonate of lime	10·0	grains.
Sulphate of lime	13·6	,,
Nitrate of lime	16·4	,,
Chloride of calcium	11·1	,,
Carbonate of magnesia	8·5	,,
Sulphate of magnesia	12·1	,,
Chloride of magnesium	9·6	,,

Inasmuch, however, as it is only the relative hardness of a water that is usually required to be known, unnecessary complication is avoided by representing that hardness in degrees, the value of which has been conventionally agreed upon by chemists. One degree is the amount of hardness that would be produced by one grain of carbonate of lime in a gallon of water: two degrees by two grains, and so on.

SOCAGE, or SOCCAGE, is service rendered by a tenant to his lord for lands, the principal ingredient of which is its being fixed and determined in its nature and quality. The certainty of the service distinguished socage from tenure in chivalry, or by knight's service, on the one hand, and from tenure in pure villeinage by arbitrary service, on the other; and therefore Littleton says, § 118, "A man may hold of his lord by fealty only; and such tenure is a tenure in socage; for every tenure which is not a tenure in chivalry is a tenure in socage."

Socage is said by old writers to be of three kinds: socage in frank tenure; socage in ancient tenure; and socage in base tenure. The propriety of the last denomination is however doubtful. The second and third kinds are now called respectively tenure in ancient demesne and copyhold tenure. The first kind is called free and common socage, to distinguish it from the two others, though as the term socage has long ceased to be applied to the two latter, socage and free and common socage now mean one and the same thing.

Besides fealty, which the tenant in socage, like every other tenant, is bound to do when required, the tenant in socage, or, as he was formerly called, the socager or sockman, is bound to give his attendance at his lord's court baron, if the lord holds a court baron either for a manor [MANOR] or for a seigniory in gross. This obligation to attend the court, it is supposed, gave rise to the name of the tenure, but the question is not without doubt.

Both forfeiture and escheat are incident to tenure in socage, as they were also to tenure by knight's service. In that species of socage tenure which is called gavelkind there is no forfeiture.

Wardship is also incident to this tenure. But this incident is not, as formerly in knight's service, a benefit given to the lord, but a burden imposed on the infant's next friend of full age, who must however be a person not capable of inheriting the estate upon his young kinsman's death.

In particular districts some of the incidents of tenure by knight's service were by custom annexed to the tenure in socage. Thus in the diocese of Winchester the lord claimed the wardship and marriage of his socagers.

Before the abolition of feudal burdens by the Commonwealth, confirmed upon the Restoration by 12 Car. II. c. 24, tenants in socage were bound to pay 20*s.* upon every 20*l.* of annual value, as an aid for making the lord's son a knight, and the same for marrying the lord's eldest daughter. This tenure was also subject to the payment of fines upon alienations.

By the above statute, the provisions of which were extended to Ireland by the Irish act of 14 and 15 Car. II. c. 19, tenure by knight's service was abolished, and all lands, with the exception of ecclesiastical lands held in free alms [FRANKALMOIGNE], were directed to be held in free and common socage, which, with the limited exception in favour of lands held in frankalmoigne, is now the universal tenure of real property throughout England and Ireland, and those colonies which have been settled by the English.

It is true that a large portion of the soil of all those countries is held by leaseholders, and in England also by copyholders; but the freehold of the land held by leaseholders and copyholders is in their lords or lessors, who hold that freehold by socage tenures.

SOCIAL CONTRACT, or ORIGINAL CONTRACT. Locke thus expounds his doctrine of the social contract ('Essay on Civil Government,' c. 8, 'Of the Beginning of Political Societies'): he says that "men being by nature all free, equal, and independent, no one can be put out of his estate and subjected to the political power of another without his own consent." By *can* he does not mean to say that it may not happen that one man shall be subjected to the political power of another, but that he cannot properly or justly be subjected without his consent; which appears from what follows:—"Whosoever therefore out of a state of nature unite into a community must be understood to give up all the power necessary to the ends for which they unite in society, to the majority of the community, unless they expressly agreed in any number greater than the majority. And this is done by barely agreeing to unite into one political society, which is all the compact that is or needs be between the individuals that enter into or make up a commonwealth. And thus that which begins and actually constitutes any political society, is nothing but the consent of any number of free men capable of a majority to unite and incorporate into such a society. And this is that, and that only, which did or could give beginning to any lawful government in the world." This doctrine is open to obvious objection. The conclusion as to the origin of "*lawful* government" by implication contains the notion that some governments are not lawful, whereas all men must and do admit that all governments which can maintain themselves are governments, and the term lawful is not applicable to that power which can declare what is lawful. The two objections which Locke mentions as being made to the theory are, 1.—"That there are no instances to be found in story of a company of men independent and equal one amongst another, that met together, and in this way began and set up a government." 2. That "it is impossible of right that men should do so, because all men being born under government, they are to submit to that, and are not at liberty to begin a new one." Locke replies to both objections with considerable ingenuity, but there are few political writers at present who will be inclined to consider his answer conclusive.

Hume, in his 'Essay on the Original Contract,' admits that "the people, if we trace government to its first origin in the woods and deserts, are the source of all power and jurisdiction, and voluntarily, for the sake of peace and order, abandoned their native liberty, and received laws from their equal and companion. The conditions upon which they were willing to submit were either expressed or were so clear and obvious that it might well be esteemed superfluous to express them. If this, then, be meant by the original contract, it cannot be denied that all government is at first founded on a contract, and that the most ancient rude combinations of mankind were formed entirely by that principle." And yet he adds, "in vain are we sent to seek for this charter of our liberties—it preceded the use of writing and all the other civilised arts of life." Consequently we cannot trace "government to its first origin," and therefore we cannot tell how government originated. But we do know, as Hume shows, that all governments of which we can trace the origin have been founded in some other way than by an original contract among all the members who are included in them. Hume further says, "that if the agreement by which savage men first associated and conjoined their force be meant (by the term Original Contract), this is acknowledged to be real; but being so ancient, and being obliterated by a thousand changes of government and princes, it cannot now be supposed to retain any authority. If we would say anything to the purpose, we must assert that every particular government which is lawful, and which imposes any duty of allegiance on the subject, was at first founded on consent and a voluntary compact." This is the real question. Those who found what they very incorrectly term "lawful government" on *an* original contract, must show us the contract. So far Hume's objection is good, and whether there was *an* original contract or not is immaterial. The question is, what was the origin of any particular government? Those who maintain that any particular government originated in a contract of all the persons who, at the time of the formation of the government, were included in it, cannot prove their case. Those who deny the original contract can show that many particular governments have originated "without any pretence of a fair consent or voluntary subjection of the people."

But an original contract, such as Hume admits, is as far removed from the possibility of proof as the origin of any particular government by virtue of a contract; nor have we any record of savage men associating to form a government. If one set of savage men did this, others would do it, and there must have been many original contracts, which contracts are the remote origin of all particular governments; but inasmuch as that origin of any particular government, which we do know, was not made by contract, and did not recognise the original contract, such government is unlawful, as those who contend for the theory of an original contract would affirm, or ought to affirm, if they would be consistent. Thus the practical consequences of the doctrine of an original contract, if we rigorously follow them out, are almost as mischievous as the doctrine that every particular government was founded on an original contract. It is true that the theory of an original contract of savage people being the foundation of government is a mere harmless absurdity, when at the same time we deny that any particular government has so originated, provided we admit that such particular government is not to be resisted simply because it is not founded on contract. Those who maintain that all existing governments rest on no other foundation than a contract, affirm that all men are still born equal—that they owe no allegiance to a power or government, unless they are bound by a promise—that they give up their natural liberty for some advantage—that the sovereign promises them these advantages, and if he fails in the execution, he has broken the articles of engagement, and has freed his subjects from all obligations to allegiance. "Such, according to these philosophers, is the foundation of authority in every government; and such is the right of resistance possessed by the subject" (Hume). This is a good exposition of the consequences that follow from the theory of every government being founded on contract.

Governments, as we now see them, exist in various forms, and they exist by virtue of their power to maintain themselves. This power may be mere force in the government and fear in the governed. Combined with the power of the government there may be the opinion of a majority in favour of the government, or of a number sufficiently large and united to control the rest; and this opinion may be founded either on the advantage which such number or majority conceive that they derive from the actual form of government, or the advantage which they and all the rest are supposed to derive from such government. The opinion of a considerable number may be strong enough to overthrow a government or to maintain it, but in either case it is not the opinion of all.

The real origin of government lies in the constitution of man's nature. Man is a social animal, and cannot exist out of society. He is of necessity born in a society, that is, a family, the smallest element to which we can reduce a state. He who requires not to live in a society, says Aristotle, must be a beast or a god. ('Politik.' i. 2). The nature of man compels him to seek union with the other sex. A man by himself is not a complete being: by the constitution of their nature man and woman must unite; and this is the foundation of a family. Those who accept the Mosaic account of the creation have there a clear statement of the origin of a family; and the father's authority is as much in accordance with the constitution of our nature as the union of the father and the mother. The various modes in which the descendants of a common pair might be detached from their primitive seats are infinite; and the modes in which they might be formed into political societies are infinite also. But if we have no account of them, it is useless to speculate what the precise modes may have been. Man, says Aristotle, is by nature a political animal; and by his nature he has an impulse to political union. He therefore follows the law of his nature by living in political society, as much as he obeys it by uniting himself with a woman. The form of any particular government, and the mode in which it may have been established, are the accidents, not the essentials, of political union, the real foundation of which is in our nature. But inasmuch as every community exists for some good end

(Aristotle), we estimate the value of any particular government by its fitness for this end, and the accidents of its form are subordinate to that for which pursuant to its nature it exists. Its origin may in many cases have been as obscure, and as little perceived, as the origin of those customs which exist in such endless variety in the world. Nobody supposes that customs originated in universal consent, or that people who follow them, or at least the majority who follow them, ever consider why they follow them. He who can trace the origin of customs can trace the origin of government.

The theory of men living in a state of nature and thence proceeding to form political societies, has apparently derived some countenance from the condition of many savages. There are perhaps people who may be said to have no government, if it be true that among some savages there is no bond of union except that of families. If this is so, each family is ruled by its head, like the families of the Cyclops (Aristotle, 'Politik.' i. 1), so long as the head can maintain his dominion. This state, if it exists anywhere, is perhaps what some people call a state of nature; but it is in fact a very imperfect state of nature, for the perfect state of nature is a political society, because it is that state to which the nature of our constitution impels us as the best. The savage in his lowest condition bears the same relation to the man who is a member of a political body, that the man who has not his senses bears to the man who has his full understanding. Both the savage and the idiot are imperfect men: they are the deviations from the course of nature.

SOCIETIES, ASSOCIATIONS. The great increase of Societies or Associations for all kinds of purposes is characteristic of the present condition of Europeans in Europe and of Europeans who have settled in other parts of the world. Association for particular objects is analogous to the great associations of political societies, but with this difference, that their object is something particular, and that they are really established and exist by the consent of the individuals who compose them.

Societies have been formed and exist for nearly every variety of object. There are societies for objects scientific and literary, sometimes called academies; for objects religious and moral; and for objects which are directly material, but in their results are generally beneficial to the whole of mankind. There are societies for objects which the members consider useful, but which other people consider to be mischievous. Generally, in this country, it may be stated that any number of individuals are permitted to contribute their money and their personal exertions for any object which is not expressly forbidden by some statute, or which would not be declared illegal by some court of justice, if the legality of such association came in question before it. The objects for which persons may and do associate are accordingly as numerous as the objects which individuals may design to accomplish, but cannot accomplish without uniting their efforts.

In some cases the State has aided in the formation of such associations, and has given them greater security for carrying their purposes into effect, as in the case of savings' banks and friendly societies. Sometimes the State grants a charter of incorporation to associations, which in many respects enables the body to transact its matters of business more conveniently. Sometimes the State perceives that it can extract some revenue from persons who associate for particular purposes, as in the case of fire-insurance offices, for all persons who insure their property in them (except farming stock, &c.) must pay the State 200 per cent. on the sum which they pay to secure their property against the accidents of fire. [Insurance, Fire.] If a man should think it prudent to invest a part of his annual savings in a life insurance, the State makes him pay a tax on the policy. A great many associations of individuals for benevolent, scientific, and such like purposes are left to direct their associations according to the common principles of law.

If lists were made of all the associations in Great Britain and Ireland, including those which are purely commercial, with an account of their objects, income, and applications of income, we should have the evidence of an amount of activity and combination that was never equalled before. How far it might be prudent to give to all associations for lawful purposes greater facilities for the management of their property and the making of contracts, subject to certain regulations as to registration of their rules and approval of their objects, is a matter well deserving of the attention of the legislature.

SOCINIANS. [Socinus, in Biog. Div.]

SODA. [Sodium.]

SODA-ASH. [Sodium.]

SODA, MANUFACTURE OF. [Sodium.]

SODA-WATER. [Aërated Waters.]

SODIUM. (Na, *natrium.*) The original name of natrium for this metal is derived from that of natron, nitron, or trona, old names of certain natural deposits of carbonate of soda which were long confounded with the true nitron or nitre (nitrate of potash). The term sodium originates from soda or sod-ash, the latter probably having allusion to the practice of burning the sods or turf of plants growing near the sea in order to obtain their ash, which is a crude carbonate of soda, known as *barilla.*

Sodium, like Potassium, was first isolated by Sir H. Davy. It may be prepared in a manner similar to, but with far greater facility than, the last-named element. Deville gives the following directions for obtaining it in large quantities. Intimately mix 717 parts of dried carbonate of soda with 175 parts of powdered charcoal and 108 of finely ground chalk; knead into a stiff paste with oil: heat in a covered iron pot till the oil is all decomposed; finally, distil, with the apparatus, arrangements, and precautions given under Potassium.

Sodium has the characteristic lustrous appearance of a metal, and is of a beautiful light rose colour. It may be obtained in quadratic octohedral crystals by the method described under Potassium. Like potassium, it speedily tarnishes by exposure to the air, owing to its great affinity for oxygen, and this occurs more rapidly when the air is moist; it requires for preservation the same precautions as have been mentioned with regard to potassium. It does not, like this metal, inflame when thrown upon water, but decomposes the latter with a hissing noise, the results being hydrogen and oxide of sodium, or soda, which, remaining in solution, exhibits the well-known alkaline character of that substance. When however it is placed on a moistened bad conductor of heat, as charcoal, it decomposes water with vivid combustion. Its specific gravity is 0.972. It is a good conductor of electricity and heat; but if too strongly heated in the air, it burns with a yellow flame.

The equivalent of sodium is 23.

Sodium combines with all the elementary gaseous bodies, two of which combinations, namely, those with oxygen and chlorine, are of great importance and utility.

Oxygen and sodium form two compounds, protoxide and peroxide of sodium; the former of these has been long known, and extensively used in various arts and manufactures. It was formerly called the *fossil* or *mineral alkali*, to distinguish it from potash, which, as being procured by the incineration of wood, was called the *vegetable alkali;* the peroxide has been discovered only since the metal was known.

Under the head of carbonate of soda we shall briefly mention the processes by which soda is procured for manufacturing purposes, stating merely at present that *protoxide of sodium*, or *anhydrous soda* (NaO) is prepared by heating the metal in dry oxygen gas. Thus obtained, it is a gray solid, resembling potash in appearance, but it is less fusible and volatile. It is extremely acrid to the taste, and is very caustic. It has great affinity for water, dissolving readily in it, and in large quantity, and the solution has strongly marked alkaline properties.

Sodium differs remarkably from potassium in some respects; thus, while both become first alkaline oxides, and afterwards carbonates, by exposure to the air, the carbonate of soda remains dry, while that of potash becomes fluid, owing to the absorption of water.

Sodium, as has already been noticed, is oxidised by decomposing water, and the solution of soda obtained, when evaporated to dryness, leaves *hydrate of soda* (NaO, HO). This is a solid white substance, greatly resembling soda in appearance and properties. It retains the water with such great affinity that it cannot be expelled by heat.

The hydrate is composed of one equivalent of soda and one equivalent of water.

Solution of hydrate of soda is largely used in the arts. It is made by boiling a tolerably strong solution of soda-ash or carbonate of soda with milk of lime until a portion of the filtrate ceases to effervesce on the addition of an acid. The strength of the solution is indicated by its specific gravity at 59° Fahr., as demonstrated in the following table by Zimmerman:—

Sp. gr.	Soda per cent.	Sp. gr.	Soda per cent.
1·4285	30·220	1·2392	15·110
1·4193	29·616	1·2280	14·506

1·2453	15·714	1·0040	0·302

Soda is met with in some mineral substances, but not so commonly as potash. It is found however in albite, or cleavlandite, a constituent of granite resembling felspar, except that it contains soda instead of potash. [Sodium, in Nat. Hist. Div.]

Peroxide of Sodium (NaO^3 ?).—This compound is formed on moderately heating sodium in oxygen gas. It burns vividly, evolving much light and heat; the peroxide resulting is of a yellowish-green colour. When put into water, it is decomposed, oxygen gas being evolved, and soda, or protoxide of sodium, remaining in solution.

It is not applied to any use, and, being decomposed by water, it does not form salts with acids.

Chlorine and sodium form only one compound, the important one, common salt, formerly called muriate of soda, and now *chloride of sodium* ($NaCl$). Of all natural soluble salts this occurs in the greatest quantity. It is met with solid, constituting *rock salt*, in solution in salt springs and in the ocean, and in small quantity in almost all spring and river water. [SALT TRADE; SODIUM, in NAT. HIST. DIV.]

This salt may be obtained artificially, either by the direct action of chlorine gas on sodium, or by saturating hydrochloric acid with soda; by evaporating the solution, common salt is obtained, which, in whatever manner or from whatever source procured, has, when pure, the following properties:—it is colourless, inodorous, has a purely saline taste unmixed with bitterness; is transparent, brittle, and easily reduced to powder; its specific gravity is about 2·125; when exposed to moist air, it deliquesces; it crystallises in cubes, which form under common circumstances is but little subject to modification. It is almost as soluble in cold water as in boiling. Water at 32° dissolves more than at 60°; 100 parts of water at 58° dissolve 36 of salt, and in a boiling saturated solution, the temperature of which is 229·5°, 100 parts of water hold 41·2 of salt in solution. A saturated boiling solution does not deposit crystals on cooling, evaporation being necessary to produce this effect; in pure alcohol it is insoluble. At a red heat common salt fuses, and on cooling it becomes a transparent brittle mass; the crystals contain no water of crystallisation, but decrepitate strongly when heated, owing to the expansion of mechanically interposed water. At a bright red heat it sublimes in the air, and tinges flame of a blue colour.

The uses of this salt have been known from the earliest ages. It is employed not only in seasoning food, but in preserving meat from putrefaction. It is used occasionally as a manure. In chemical manufactures it is employed for preparing hydrochloric acid, sulphate and carbonate of soda, and several other salts, and in the preparation of soap.

Sodium combines with fluorine, bromine, iodine, sulphur, phosphorus, &c.; the compounds which they form are unimportant, not being extensively applied to any useful purposes. Their formation is accomplished by methods similar to those employed in the preparation of the corresponding salts of POTASSIUM.

Salts of Oxide of Sodium, or Oxisalts of Soda.

It is perhaps scarcely requisite to state that these salts are never prepared by directly acting upon the metal sodium, although for purposes of curiosity they might all of them be so procured. The first which we shall notice is—

Nitrate of Soda (NaO, NO_5).—This salt may be prepared either by adding the metal, or soda, its oxide, to nitric acid; as a natural product it has, however, of late years been largely imported from Peru, where it forms a deposit similar to that of nitrate of potash in India. Nitrate of soda has a cooling saline taste, is inodorous and colourless; in a moist atmosphere it deliquesces; it readily crystallises, and the form of the crystal is an obtuse rhomboid; so obtuse indeed, and so near a cube, that the salt was originally called *cubic nitre*, to distinguish it from potash nitre, the crystals of which are prismatic. According to Gay-Lussac, 100 parts of water at 32° dissolve 73 parts of this salt; and at 212°, 173 parts: water at 60° dissolves half its weight. It is sometimes found with crude nitrate of potash.

Like nitrate of potash, it deflagrates with charcoal; but owing to its property of attracting moisture, it cannot be used in the manufacture of gunpowder. It is, however, used largely in making nitric acid, sulphuric acid, and as a manure.

There are three compounds of carbonic acid and soda; namely, 1, *carbonate*; 2, *sesqui-carbonate*; and 3, *bi-carbonate*.

1. *Carbonate of Soda* ($NaO, CO_2 + 10\,Aq.$).—This salt, formerly called *subcarbonate of soda*, was obtained from *barilla* or *kelp*: the former being the ashes of the *Salsola soda*, and prepared in Spain; the latter the ashes of burnt sea-weed, manufactured in Scotland. Since the duty has been taken off common salt, carbonate of soda is prepared, for the numerous uses to which it is applied, by first converting common salt into sulphate of soda by means of sulphuric acid, and then treating the sulphate, or *salt-cake*, as it is called, with small-coal and chalk in a reverberatory furnace; the result is a mixture of carbonate of soda and oxysulphide of calcium, termed *ball-soda*, or *black-ash*, when this is treated with cold water, the oxysulphide remains undissolved, while the carbonate of soda is taken up by the water, and by evaporation to dryness yields what is called *soda-ash*.

Carbonate of soda is a colourless, inodorous salt; it is devoid of smell, but has a disagreeable taste, though less so than carbonate of potash; it is readily soluble in water. The primary form of this substance, when crystallised by moderate evaporation of the solution, is an oblique rhombic prism. The crystals are frequently very large. They contain about 62 per cent. of water, the greater part of which they lose by exposure to the air, and efflorescing, fall to powder. At high temperatures the salt becomes fluid and boils. Water at 60° dissolves half its weight of carbonate of soda, and boiling water considerably more. The solution possesses the alkaline property of turning vegetable yellows brown. Like other carbonates, this salt is decomposed by the stronger acids, with effervescence of carbonic acid; and by lime, which separates its carbonic acid, it is rendered caustic.

The quantity of this salt prepared and used is enormous; it is required in making soap, and crown and plate glass, and for numerous other purposes.

2. *Sesqui-carbonate of Soda* ($2NaO, HO, 3CO_2 + 3Aq.$).—This compound is found native in Hungary, and also near Fezzan in Africa. By the natives it is called *Trona*. It is found in hard striated crystalline masses, is not altered by exposure to the air, and is readily soluble in water.

This salt appears to be formed when a solution of the carbonate of soda is heated with carbonate of ammonia, and probably also when a solution of the bi-carbonate is heated. Its taste is less alkaline than that of the carbonate, into which it is converted, when strongly heated, by losing one-third of its carbonic acid.

Bi-carbonate of Soda ($NaO, HO, 2CO_2$).—This salt may be formed by passing carbonic acid gas into a solution of the carbonate of soda; it is a crystalline granular compound. It is produced on the large scale by exposing crystals of carbonate of soda to a current of carbonic acid gas.

Bi-carbonate of soda has a very slightly alkaline taste, and acts very feebly on turmeric-paper. It requires about twelve times its weight of water for solution. When the solution is boiled, it loses one-fourth of its carbonic acid, and is converted into sesqui carbonate; at a red heat it loses all its water and half its carbonic acid, carbonate of soda resulting. It resembles the sesqui carbonate in giving no precipitate with the salts of magnesia till heated; and they both differ from the carbonate in this respect. It is used in medicine. *Soda water* is, or at least should be, a solution of bi-carbonate of soda in water charged with carbonic acid gas under pressure. [AËRATED WATERS.]

Sulphate of Soda ($NaO, SO_3 + 10Aq.$), formerly called *Glauber's salt*, may be formed by the direct combination of the acid and alkali; it is, however, generally prepared by decomposing common salt, as in the preparation of hydrochloric acid, or of carbonate of soda. It has also been met with in nature, but not largely. [SODIUM, in NAT. HIST. DIV.]

This salt is readily soluble in water, and the solution by evaporation yields colourless transparent prismatic crystals, the primary form of which is an oblique rhombic prism. It has a very bitter taste; effloresces when exposed to the air, by losing water of crystallisation. Boiling water dissolves its own weight of this salt, and water at 60° one-third of its weight. It is, however, most soluble at 93° Fahr.; at that temperature 100 parts of water will dissolve 50·6 parts of the salt. A boiling saturated solution of sulphate of soda may be cooled and kept for months without any crystals forming in it, provided that air be excluded; let, however, a crystal of the sulphate, or any solid matter, even a particle of dust, be dropped into the liquid, and the whole then shoots into crystals with considerable elevation of temperature. Sulphate of soda is insoluble in alcohol. When exposed to heat it first undergoes watery fusion, by melting in its water of crystallisation; when the water has been expelled, it becomes opaque white, and at a red heat it melts.

An *anhydrous sulphate* of soda, and a hydrate containing $NaO, SO_3 + 7Aq.$ may also be obtained. *Bisulphate of soda* contains $NaO, HO, 2SO_3$.

Sulphite of Soda ($NaO, SO_2 + 7Aq.$) is formed on passing sulphurous acid gas over carbonate of soda. It is used by paper manufacturers, under the name of *antichlor*, for removing the last trace of chlorine from their rag-pulp. *Bisulphite* of soda contains $NaO, HO, 2SO_2$.

Silicates of Soda. [SILICON; GLASS.]

Acetate of Soda. [ACETATE.]

Phosphoric Acid combines with soda to form several compounds. [PHOSPHORUS.]

Borate of Soda is a compound of boracic acid and soda. [BORON.]

For an account of numerous other salts of soda we must refer to chemical treatises; those whose properties we have detailed being merely the most useful.

General Properties of the Salts of Sodium.—Unlike the salts of potash, there is no acid nor any metallic oxide which forms a perfectly insoluble compound with the salts of soda, so that they cannot be precipitated in combination from solution. The best mode of distinguishing between these two alkalies is, by the yellow colour which soda salts communicate to the blow-pipe flame, salts of potash giving a violet tinge. They are separated from each other by taking advantage of the insolubility of the double chloride of platinum and potassium, and the great solubility of the corresponding sodium salt.

SODIUM, *Medical Properties of the Preparations of.* Sodium, when in the state of an oxide, is termed the mineral alkali, in contradistinction to potash, or the vegetable alkali.

Sodium possesses the ordinary qualities of a fixed alkali, but notwithstanding the resemblance it has to potash, the preparations, even with the same acid, present some differences which may be here pointed out.

In the oxidised state, or soda (pure or caustic), sodium is not employed in medicine to counteract acidity; nor in surgery to form an ulcer or to open abscesses, though for this latter purpose it possesses some advantages over hydrate of potash, inasmuch as it is not liable to spread or run.

It is only when in combination with carbonic acid that it is used to correct acidity. It exists in three states, namely, carbonate, sesquicarbonate, and bi-carbonate: the causticity of these is less in proportion to the increase of the acid. These preparations, administered in various ways, but chiefly in solution, are much used to counteract real or presumed acidity of the stomach. The abuse of the analogous preparations of potash has been already pointed out. [POTASSIUM.] The same caution is necessary as to soda-water, when that really contains any carbonate or bi-carbonate of soda, as it not unfrequently consists only of carbonic acid compressed into the water. The saline draughts so commonly employed in the medical practice of this country are liable to the same objection, and in all cases of debility, especially in the phosphatic diathesis, do infinite harm. For an opposite reason, they are extremely serviceable in all inflammatory complaints: the period when they should be discontinued can only be determined by an intelligent medical attendant.

The preparations of soda possessed of purgative properties are—the sulphate, or Glauber's salts, the phosphate, and the triple salt, called sodæ-potassio-tartras, or Rochelle salts, of which potash is also a constituent. Of these it is only necessary to observe that of the sulphate a much larger dose is required than of the corresponding salt of potash; and that the phosphate, being nearly tasteless, and extremely mild in its action, is a very proper aperient for delicate persons. A nearly similar character belongs to the Rochelle salt, but as this is decomposed in the stomach, it is as hurtful as the common saline draughts in cases of debility, though very beneficial in inflammatory disorders, particularly in both acute and chronic duodenitis. The same remark is applicable to the so-called Seidlitz powders formed with Rochelle salt and bi-carbonate of soda, to which, when dissolved, a solution of tartaric acid is added, and the mixture drank in the state of effervescence. The most quickly acting aperient is a Seidlitz powder dissolved in warm water; this is most proper at the commencement of common colds, influenza, and inflammatory diseases, but it should not be repeated without medical sanction, especially in influenza, where extreme debility speedily ensues.

The preparations of soda possessed of diuretic properties are the bi-borate and the acetate. The former of these has been already treated of [BORAX], and the second is rarely used, though, from not deliquescing, it has the advantage over acetate of potash, that it can be administered in the form of powder.

Chloride of sodium possesses purgative and emetic properties, which render it useful as a domestic remedy. Its other uses have been already pointed out. [BATHING; ANTHELMINTICS; FOOD.] Along with lemon juice it is a great means of checking sea-sickness.

Chloride or hypochlorite of soda is a powerful disinfecting agent. [ANTISEPTICS.] It is of great utility in the malignant sore throat of scarlatina, and in diphtheria.

Bisulphite of soda is a powerful antiseptic. It effectually checks or prevents fermentation. (Macculloch 'On Wine Making.') It retards the decomposition of animal substances, and for that purpose is used in Parisian dissecting-rooms.

Hypophosphite of soda is sometimes of use in the early stages of consumption; also in anæmia and chlorosis.

Valerianate of soda is a useful anti-spasmodic in some forms of indigestion, with spasms from unhealthy acids in the stomach.

SODIUM-ETHYL. [ORGANOMETALLIC BODIES.]

SOFTNESS is a condition of solid bodies in which the particles are held together by a cohesive power of small intensity: in consequence of this, such bodies change their figures upon the application of a small degree of force; and they do not recover their previous forms upon its removal.

This condition is the opposite of hardness, in which the particles are held together by a power of cohesion so great that they cannot be separated by any force which it may be convenient to apply to them. No body in nature is known to possess either of these qualities absolutely; but in contemplating the mechanical actions of soft bodies, balls of wet clay are generally used, while blocks of wood acting against one another in the directions of their fibres are frequently used to illustrate the effects of hardness. Balls of glass or ivory, or steel springs, serve to show the mechanical actions of elastic bodies. [COLLISION OR PERCUSSION OF BODIES.]

SOIL. Wherever the surface of the earth is not covered with water, or is not naked rock, there is a layer of earth, more or less mixed with the remains of animal and vegetable substances, in a state of decomposition, which is commonly called the *soil*.

The nature and composition of the soil, and consequently its greater or less aptitude to the growth and maturity of vegetable productions, depend on the composition, the proportion and the mechanical structure of the various substances of which it consists. When the soil is favourable to the chemical action by which the elements are combined to form vegetable substances, and admits that quantity of air and moisture without which this chemical action cannot take place in any given climate or temperature, vegetation goes on rapidly, and all the plants which are suited to the climate grow in the greatest perfection, and bear abundant fruits.

It is not however very frequently the case that a soil possesses all those qualities on which great fertility depends. So many circumstances must concur to make a soil highly fertile, that the great majority of soils can only be made to produce abundantly by being improved by art both in their texture and composition. Hence the practice and science of agriculture, which is founded on experience, but to which every progress in science also affords great assistance, by the additional light which every new discovery throws on the true theory of vegetation.

There are various modes of distinguishing soils, without entering into a minute analysis of their component parts. The simplest and most natural is to compare their texture, the size and form of the visible particles of which they are composed, and to trace the probable source of their original formation from the minerals which are found around or below them, or the rocks from which they may have been slowly separated by the action of the elements. The science of geology, which teaches the relative position and nature of the minerals of which the outer crust of the earth is formed, is consequently of the greatest utility in aiding us to compare different soils and in ascertaining their composition.

The knowledge which geology imparts is however not sufficient for the minuter classification of soils; for it is found by experience that the soils which lie over or near the different strata, as they appear near the surface, vary greatly, although they retain some general character which distinguishes them from others. The streams which descend from the hills, and flow towards the valleys, and through them to the sea, carry to a great distance the minuter portions of the minerals which they flow over in their course, while the larger and heavier are deposited much sooner. Hence the heterogeneous mixture of various earths and stones, and their stratification in thin layers, as is often found when a soil is examined which has never been disturbed by cultivation.

It is not sufficient to class soils according to the substance which predominates, as has been usually done, such as sandy, gravelly, chalky, or clay soils; for this gives very imperfect information respecting their nature or fertility; neither is it altogether sufficient to class them according to any particular geological formation.

The soils which have been evidently formed from the rocks which are supposed to be of secondary formation are fertile according to the proportion of the earths of these rocks which they contain.

Argillaceous earth exists in some proportion in almost every rock. It has the property, when mixed with other substances, as silica or lime, of fusing into a stone of great hardness and insolubility. In this state its effect on the soil is not to be distinguished from that of silica; and by burning common clay, or clay mixed with carbonate of lime, a sandy substance is produced resembling burnt brick, which tends greatly to improve the texture of those clays which contain little or no sand in their composition. It must be remembered that the stiffest clays contain a large portion of silica in an impalpable state; but this, instead of correcting their impermeable and plastic nature, rather adds to it. It is only palpable sand which with clay forms what is commonly called loam, and which, when the sand is in due proportion with a mixture of organic matter, forms the richest and most easily cultivated soils. Some of the rocks of secondary formations contain a considerable portion of alumina and lime; and when these earths meet with crystallised sand, a compound, or rather a mixture is formed, which has all the requisite qualities, as to texture, to produce the most fertile loams. The only deficiency is that of organic matter; but this is so readily accumulated wherever vegetation is established, or can be so easily added artificially, that these loams may always be looked upon as the most favourable soils for the usual agricultural operations; and if a considerable depth of loam is found, which neither retains water too long nor allows it to percolate too rapidly, it may be looked upon as a soil eminently capable of the highest degree of cultivation, and on which no judicious outlay of labour will ever cause loss or disappointment to the farmer.

Thus, the greensand which lies under the chalk, and appears near the surface in several parts of Britain, consists of silicious, argillaceous, and calcareous earth, intimately combined and in a high state of subdivision, and yet not forming a compact paste with water so as to dry in hard lumps, but having rather the loose appearance and granulation of fine sand, whence its name. On this soil are found the finest wheats; but such is the variety of its form as it approaches towards the chalk or crystallised sand, or the plastic clay, that the soils which it forms have every degree of texture, from loose sands to stiff marls, whose chief use is to mix with other soils and improve them. In general however it may be said that the soils of which the greensand forms a considerable part are productive and easily cultivated, and that they repay the labour and manure expended on them better than most others. A narrow strip of this sand crosses Bedfordshire, and in the neighbourhood of Sandy and Biggleswade are raised some of the finest culinary vegetables which come to the London market. This sand, though light in appearance, and very easily worked, contains much of the impalpable substance mentioned before; and this, with careful cultivation and manuring, makes it peculiarly suited for gardens as well as for corn-fields. In its natural state it is easily distinguished from other sands by certain dark particles in it, which give it the greenish hue from whence it has been called greensand, and also by its effervescence with strong vinegar or any other acid.

Chalk is perhaps the mineral most widely spread throughout Britain. The chalk formation of itself forms a very poor and barren soil. In the course of ages the surface of the chalk has been covered with a thin coating of soil, consisting of chalk and organic matter chiefly. On this soil the finest and most aromatic plants are found, but of small dimensions, affording a sweet short pasture, much relished by sheep. The constant treading in of the dung of the sheep, and the stimulating effect of their urine, gradually increase the quantity of vegetable and animal matter; and thus the turf becomes close and rich: but if this thin coat be disturbed by the plough and mixed with the chalk below, it will, after one or two tolerable crops of corn, be reduced to its original sterility; and it requires ages to restore the fine pasture which once covered it. Such is the case with those hills which are called the South Down Hills, in Sussex and Wiltshire, on which are bred the excellent sheep which bear that name.

But the chalk has in many places been carried down by the rains and transported in a comminuted state to the sandy or clayey valleys around them, and by the mixture has greatly improved both, forming various loams and marls in themselves highly fertile, or very useful in increasing the fertility and texture of other soils. Chalk has the peculiar property of neutralising acids of every description, and of preventing their formation in the soil by the fermentation of vegetable substances; while it assists in that slow decomposition which causes the evolution of carbonic acid, and thereby assists and invigorates vegetation. The presence of carbonate of lime, if it does not exceed a third part, and if it is intimately blended with alumina and silica, is always a sign of fertility, especially when loose sand is mixed with it, so as to form one-half of the whole soil. This is called a light calcareous loam, and is usually found on the slopes or around the base of chalky hills.

The Weald clay consists of very minute particles of alumina and silica, forming a tough unctuous earth, fit for the growth of oaks, with very few stones or visible particles. This soil is found in Sussex and Kent chiefly. The plough cuts it into continuous slices, when it can be ploughed, which is only in a certain state of moisture; for when it is dry the surface is as hard as a rock, while the subsoil is continually moist, the water being unable to pass through its pores. It has the most unpromising aspect, drying into hard lumps like brick, and apparently incapable of being brought to such a state of mellowness as to admit the seed or cause it to vegetate; yet this stubborn soil may be rendered fertile by tillage, draining, and exposure to frost in winter; and its tenacity may be corrected by the application of lime, ashes, and other substances, especially fresh stable-dung, which interpose and prevent the clods from re-uniting into one tough impervious mass. Lime and chalk do this most effectually; and when the weald clay has been brought to a looser texture, it produces beans, wheat, oats, and clover in great perfection.

The system of complete under-draining by parallel drains, at the distance of from 10 to 20 feet, which carries the moisture into the surrounding ditches, has in many instances so greatly improved the weald clays, that those who had formerly attempted to cultivate them can scarcely believe their eyes when they see the abundant crops produced. Subsoil ploughing has also done wonders after complete draining, in some cases rendering the soil so mellow and loose as to allow of the cultivation of turnips, especially the Swedish. As clay soils predominate in England, and their improvement has been almost despaired of, it is of great importance that it should be generally known that no soils repay the cost of improvement better than clays, provided the surface be such as to admit of perfect draining.

Another clay is called the Oxford clay. This is of a bluish colour, which alters on exposure to the air, probably from a change in the oxidation of the iron which it contains. This clay is favourable to the growth of grass, and some of the richest pastures in Wiltshire and Oxfordshire have it for a subsoil, over which the decomposition of the roots and leaves of the grasses has formed a layer of vegetable mould of the highest degree of fertility. In the fens of Lincolnshire, the Oxford clay is covered by a coat of peat, formed by the decomposition of aquatic plants, which have accumulated wherever the water had no natural exit. When these fens were laid dry by an extensive system of draining, the peat was converted into a rich soil by the admixture of the clay which was found under it.

The *Oolite* formation contains much carbonate of lime, cemented by an unctuous earth into various sorts of stone. The soil which lies over them, and which is of nearly the same nature, but broken and disunited, is various in its qualities. Sometimes it is of great fertility, and sometimes nearly barren, according as the impalpable matter in it abounds and contains a due proportion of the different earths, or it resembles a loose chalky sand, in which moisture is retained with difficulty. In the first case, it produces every kind of grain in abundance with moderate cultivation; in the latter, it requires a great outlay of manure, which readily disappears, and then it is justly called a poor hungry soil.

On the red-sandstone is found a soil which is usually of the finest quality. The fine loose soils of Devonshire and Somersetshire are of this description. It unites most of the requisites of a good soil, both in its texture, neither too close nor too loose, and in the impalpable matter in its composition. It is peculiarly adapted to the growth of potatoes and all roots which form the basis of a judicious cultivation. When it contains a proper portion of calcareous earth, it may be reckoned amongst the most fertile soils; and where this is deficient, the addition of lime or chalk is the best means of improving it. The calcareous earth seems greatly to add to the effect of the usual manures, so that a much smaller portion is required to produce good crops.

Each distinct formation gives rise to a great variety with respect to fertility, even where the basis remains the same: but it is of great importance to the farmer to ascertain the general nature of the rocks and strata on which his farm is incumbent.

The alluvial soils formed by the deposit of a variety of earths in a state of great division, and mixed with a considerable portion of organic matter, form by far the most productive lands. They will bear crop after crop with little or no addition of manure, and with a very slight cultivation. These soils are found along the course of rivers which traverse extensive plains, and which have such a current as to keep very fine earth suspended by a gentle but constant agitation, but not sufficiently rapid to carry along with it coarse gravel or sand. Wherever there is an obstruction to the current and an eddy is formed, there the soil is deposited in the form of mud, and gradually accumulating, forms those alluvial soils which are so remarkable for their fertility when carefully protected from the inroads of the waters. In these soils the impalpable matter greatly predominates; but the intimate mixture of the earths with organic matter prevents their consolidating into a stiff clay; and the gases which are continually evolved from the organic matter keep the pores open, and give scope to the growth as well as the nourishment of the roots. It is in the alluvial soils principally that an accurate analysis is useful; because the proportion of their constituent parts varies in innumerable degrees. It may be laid down as a general rule, that the most fertile of these soils are those in which the earths are nearly in equal proportions, silica, however, being the most abundant, with about 10 per cent. of organic matter; a greater proportion of this last would form too loose and spongy a soil to bear good crops of corn, especially of wheat. But 4 per cent. of vegetable matter, with a good mixture of earths, and some phosphate of lime from the decomposition of bones and marine shells, produces a very good wheat soil. The rich warp-lands along the Humber are artificial alluvial soils, and although they contain but a small proportion of organic matter, are highly fertile after their first deposition, but it is observed that they gradually become more tenacious and difficult of cultivation as this humus is carried off by the crops; and that it is soon necessary to add animal and vegetable manures to supply its deficiency.

Organic matter is no doubt essential to great fertility in a soil, but some soils require more of it than others. In every stage of its spontaneous decomposition it keeps the pores of the soil open, and admits, if it does not even attract, air and moisture to the fibres of the roots. In all rich soils which have been long cultivated, especially in gardens, there are particles of a dark colour and fibrous texture, which in the microscope appear like minute logs of charred wood. These keep the soil open, and supply carbonic acid, when the air reaches them. A proper texture seems an indispensable condition of fertility. It is much easier to supply the deficiency of vegetable matter in a soil, which at best forms but a very small portion of it, than of silica or clay, which should enter into its composition in the proportion of one half or a third of the whole. It is practicable to carry lime or chalk upon soils which do not contain calcareous matter; clay may also be carried upon loose sandy soils, where it can be found below the surface, or at a moderate distance; but if a soil is very deficient in silica, it requires so large a proportion of this earth to give porosity to stiff clay, that it very seldom can repay the trouble and expense. Hence the difficulty of bringing poor wet clay soils into a fertile state, except where an abundance of chalk and vegetable manures can be easily procured. In this case the perfect draining of the land, and exposure of the ploughed surface to the frosts of winter, with the addition of chalk and manure, produce such an alteration in the texture of the clay, that by continuing the improving process it is entirely changed into a mellow and fertile loam. The burning of a portion of the retentive subsoil into a brick-like earth gives it a porosity which renders it mechanically similar to silicious sand, and converting the iron which all these clays contain into a peroxide, the soil is thereby greatly improved in fertility; for it seems that iron, in a state of slight oxidation, or combined with any acid, is hurtful to vegetation, whereas the red peroxide is not only innocuous, but seems to have fertilising properties.

In ascertaining the value of a soil for the purposes of agriculture, two circumstances should be carefully noticed. The first is the permeability of the soil to water; and the second is its power of absorbing moisture from the atmosphere. To ascertain the first, it is only required to place an equal weight of different soils in glass tubes of equal diameter, pressing them so that they shall occupy equal spaces, but not filling the tubes. Then pour an equal quantity of water over each soil, and place them upright with cups under them. Examine which has the surface first dry, and how much water runs through each in a given time. That which presents a dry surface, while it holds most water in its pores, is probably the best. To ascertain the comparative absorption of moisture, the soils are dried in pairs on a plate of metal heated by steam, or at a heat of 212°, to expel the water. They are then placed in equal quantities in similar flat cups or dishes, and placed in opposite scales of a balance, and poised. The apparatus is exposed to a moist atmosphere out of doors, or in a cellar, and occasionally examined. That which is heaviest is, in general, the most fertile.

It is often useful to ascertain roughly the composition of a soil, without having time or opportunity to make accurate experiments. A graduated glass tube, which can be carried in the pocket, and a small phial with a ground stopper, containing diluted muriatic acid, and secured in a wooden case for fear of accident, is all the apparatus required. A little of the soil is taken and moistened with water; a few drops of the acid are poured on; and by the greater or less disengagement of bubbles the proportion of calcareous matter is guessed at, and its presence proved. The soil mixed with water is poured into the glass tube and well shaken. In a few minutes the coarse sand is deposited: shortly after the finer sand, and, lastly, the clay and impalpable matter, of which the lightest remains longest suspended. Distinct rings can be observed in the deposits, and the graduated tube shows their proportion. A person accustomed to this method will guess with great precision the general qualities of the soil; and when the geological structure of the neighbourhood and the nature of the subsoil are taken into consideration, the value of the land for pasture or cultivation is guessed with little danger of making very glaring mistakes. To surveyors and valuers this method is of very great help, when other means are not at hand. Among the properties of soils of the greatest agricultural importance must be named the absorptive powers which they possess over ammoniacal and other valuable ingredients of manures, either volatile or soluble, which would otherwise be wasted when applied to the land. This fact, first observed by Mr. Thompson, M.P., has since been investigated by Professor Way, and explains the economy of autumnal manurings and top-dressings in the winter season, when vegetation is inactive and unable at once to turn to account artificial stores of food for plants.

In practice, soils are usually divided into light, mellow, and stiff; but this gives very little information, there being every imaginable variety in each of these. There are still minute circumstances which produce great fertility or the reverse, and which it is difficult to investigate. An accurate chemical analysis, which, however, is a process requiring the service of the educated chemist, joined to a careful mechanical examination, and very correct accounts of the average produce under different systems of cultivation, can alone give us a scale according to which the natural fertility of different soils can be classed; and this must be the work of time and industry joined to science and practical knowledge. Directed as it is to the detection and estimation of ingredients, many of which occur in very small proportion, the process of chemical analysis is one which cannot be undertaken by the farmer. It is sometimes useful to him, however, to know the exact composition of his soil, and the chemist is thus sometimes able to point out the causes of infertility, and so enable him to remove them. When, therefore, he is at a loss, such an analysis may be the guide he needs; and in a deficiency of phosphate of lime, or an excess of chloride of sodium, or a deficiency of organic matter, or in the presence of iron salt which is thus detected, he may read the cause of his failure, and so be able to remove it.

SOILING is the name given in agriculture to the mode of feeding horses and cattle in the stable or yards with food brought to them as it is cut in the meadows or fields. The great advantage of soiling cattle is the increase of manure of the best quality, which is thereby produced; and this circumstance alone can counterbalance the great trouble and expense incurred in cutting and carrying all the green food from a distance to the farmyard.

The system of soiling is not very generally adopted in British husbandry, it being so much easier to allow the cattle to crop their food in the pastures; but in those countries where property in land is greatly subdivided, and where farms are small and good pastures scarce, as in Flanders, France, and Switzerland, especially where the vineyards render manure scarce and dear by taking a considerable portion of it and returning none, there the soiling of cattle is almost a matter of necessity. A cow or ox requires from two to three acres of pasture or meadow to feed it all the year round, allowing a portion for hay. But by raising clover, lucern, sainfoin, tares, and other green crops, one or two cows can be fed with the produce of one acre, especially if a portion is in mangold wurzel or other succulent roots. Thus the straw of the white crops is converted into excellent manure, and the land kept in a state of fertility.

In proportion as a farm is larger in extent, so the expense of soiling increases, both from the distance of the fields where the green crops grow, and from the same distance to which the dung has to be carted. There is a limit therefore to the soiling system, unless there be many yards or stables in different parts of a farm, so as to subdivide it, and make each yard the centre of a distinct system of soiling, with fields near at hand for the green crops. In almost every experiment on a large scale it has been found that soiling was only a certain mode of purchasing dung, and that it often was more expensive to procure it in this way than to send to a considerable distance to purchase it in towns. Where it cannot be purchased at all, there are no other means, in many situations, of producing a sufficient quantity; and the trouble and expense of soiling must be submitted to. In almost every case where sheep can be folded to feed off the crops, the soiling of cattle is a loss, because the sheep pay something for their food; the cattle in the stall do so less frequently.

But there are animals which must be fed for the work of the farm, such as horses or oxen; and these are much more profitably and economically fed by soiling than by any other means. A horse or ox, if he works eight or ten hours, has no time for rest if he has to crop his food from a short pasture, however sweet; whereas an abundant supply of clover, lucern, or tares enables him to take a hearty meal and lie down to rest. He wants no corn with this food, and does his work without losing flesh or activity.

There is nothing easier in a mild climate, and especially a moist one, like Britain or Ireland, than to have a succession of green food from the beginning of spring to the end of autumn, and afterwards a succession of succulent vegetable food through the winter. Rye and winter barley, sown early in autumn, will be ready to cut as soon as the mild weather of spring commences; some sown later with winter tares, and the young clover, which has not been cropped in autumn, will succeed. After this come artificial grasses, as Italian rye-grass and the grass of water-meadows mown early; although this last is not such hearty food for working cattle; but when joined to a mixture of oats and cut straw, their watery nature is corrected. Clover and spring tares (when these last are sown at proper intervals), lucern and sainfoin (if the soil is suited to them), will afford a constant and abundant supply to the scythe which cuts the daily allowance. It is prudent to provide against failure, and have more land in these crops than is absolutely necessary, because the surplus can always be made into hay or reserved to ripen its seed; and these green crops, valuable as they are, far from deteriorating the soil, clear it of weeds, and render it more fit to bear corn afterwards. Turnips, carrots, and mangold wurzel provide with hay and straw the winter food. And by steaming the roots or pulping them, and so mixing with chaff of hay or straw, a palatable and nutritious food may be provided at small expense. In these cases soiling is profitable and economical.

It is generally thought in those countries where the soiling system is most universally adopted, that it is best to allow the green food to remain twelve or twenty-four hours after it is cut, before it is given to cattle. This may be prudent with cows and oxen, which are apt to eat voraciously, and are subject to be hoven from the fermentation of the green food in the paunch or rumen: but, excepting in the case of young vetches, which are more physic than food, for horses there is little danger; and if the food is not wet with dew or rain, the fresher it is eaten the better it will nourish the animal, and the more he will relish it.

If any one is desirous of calculating the expense of soiling any number of beasts, he has only to reckon what time of men and horses it will take to cut the food and carry it to the cattle, from the average distance of the fields in which it can be raised in succession. Much of their time is lost in the morning and evening in going backwards and forwards from the field to the yard; for there can scarcely be an establishment so large as to keep them employed a whole day; and if there were, the fields must be so large and so distant, as to greatly increase the expense of carriage. Not to enter into minute calculations, it is fully proved, that, to a certain extent, soiling is profitable and economical, when it can be done before and after the usual hours of labour; but that when undertaken on a large scale in any one locality, it is usually attended with loss, the manure produced being purchased at too great a price.

If a labourer who has an allotment of half an acre of good light land would devote it entirely to raise food for a cow, his wife and children cutting the food and tending the cow in a small yard with a shed, or in an airy cow-stall, he would find that he had a much greater clear profit, than if he had sown his land every year with wheat, and had always a good crop, which last supposition is improbable. There would be no better stimulus to industry than to let a piece of land for this purpose to every man who could purchase a cow and feed it by soiling.

SOL, in music, the name given, in sol-fa-ing, by the English, Italians, and French to the fifth of the scale; and by the two last also to the sound called G by the Germans and English. [SOLMISATION.]

SOLANINE, a vegetable alkaloid obtained by Desfosses from the berries of the *solanum nigrum*, and the fruit of the common potato.

In appearance solanine resembles sulphate of quinine, but the crystals are finer and shorter; it restores the blue colour of litmus when reddened by an acid; dissolves in acids, and is precipitated from them by the alkalies. The hydrochlorate and acetate of solanine have a gummy appearance when evaporated to dryness, but the sulphate and phosphate are crystallisable. It is extremely poisonous: a grain of it, dissolved in dilute sulphuric acid, killed a rabbit in six hours. The analyses which have been made of this alkaloid do not accord. The following are the numbers obtained by Blanchet and O. Henry respectively.

	Blanchet.	O. Henry.
Hydrogen	8·9	9·14
Carbon	62·0	75·00
Oxygen	27·5	12·78
Azote	1·6	3·08
	100·0	100·00

SOLA'NUM DULCAMA'RA, an indigenous perennial climbing plant, common in wet and shady places, especially hedges. It has a remarkably zigzag stem, with alternate leaves, the lower ones lanceolate, entire, the upper hastate; the flowers resemble those of the potato, but are smaller, and are succeeded by a cluster of red berries. This plant is called *woody* nightshade, to distinguish it from the *Atropa belladonna*, or *deadly* nightshade. The young twigs or tops are officinal, and they should be gathered in spring, before the flowering of the plant, or in autumn while the leaves are yet *fresh*, as much activity seems to belong to the leaves, and the twigs are best from plants about three years old. When fresh, the plant has an unpleasant odour, which is in a great measure lost by drying, as is also a large portion of water. The taste is at first bitter and slightly acrid, then sweet; hence the name *bitter-sweet* given to it.

Ten pounds of the dried twigs yield two pounds of extract. According to Pfaff, 100 pounds of perfectly dried stems yield a bitter-sweet extractive (picroglycion), 21; vegeto-animal matter, 3; gummy extractive, 12; gluten with wax, 1; resin with benzoic acid, 2; gum, starch, salts (chiefly of lime), 6; and woody fibre, 62. Solanina (solania) has been found by Desfosses. Whether picroglycion, called also dulcamarin, and dulcarin, is a distinct principle, or a combination of solanina with sugar, is doubtful.

Bitter-sweet, when taken fresh, has a slightly narcotic influence, causing also nausea, vertigo, and a dryness of throat, like other solanaceous poisons. If delirium display itself, it is always of a most frantic kind. Perspiration or an increased discharge of urine generally occurs, followed by gentle purging.

Bitter-sweet is chiefly employed in cutaneous diseases, especially of the scaly kind, such as lepra; it may be given internally, while a strong wash of it is applied externally. It is also useful in some vesicular diseases, such as herpes and eczema. In these its virtues as an external application may be increased by dissolving in it sulphuret of potass. This combination relieves most effectually the intolerable irritation of these complaints.

It is usually ordered in the form of decoction, but long boiling is destructive of its powers. Slow simmering is preferable. The extract, when prepared from the fresh plant with a low degree of heat, is a good form for internal administration, as it may be combined with antimonials.

In cases of poisoning by the berries, often mistaken for currants, the stomach-pump should be used as speedily as possible, and moderate venesection is of service.

SOLAR CYCLE. [PERIODS OF REVOLUTION.]

SOLAR ECLIPSE. The phenomena of an eclipse of the sun resemble those of the moon in one respect only, namely, that the body of the luminary disappears. In all other respects there is so great a difference, both in the cause of the phenomenon and its attendant circumstances, that it is a pity one term, eclipse, should be used in senses so different. In the first place, the disappearance of the moon arises from the earth intercepting the light which she ought to receive, while that of the sun is the consequence of the moon coming between the sun and the earth. The body of the moon is never absolutely hidden, and is even slightly visible through a telescope during the darkest eclipse: but the body of the sun is really hidden by the intervention of the opaque substance of the moon. Again, the phenomena of an eclipse of the moon are the same for every point of the earth at which they are visible: the beginning, middle, and end of the phenomenon happen at the same instant of absolute time everywhere, and the same portion of the moon is hidden from all the earth at the same instant. But in a solar eclipse, it entirely depends upon the position of the spectator whether there is any eclipse at all; and of two persons at different parts of the earth, at the same instant, one may see the sun totally eclipsed, while the other may, by the brightness of the sun's rays, not know that the moon is almost close to him. A screen held before a candle may be an eclipse of the candle for one person in the room, but not for another, on account of their difference of place; this is an illustration of the solar eclipse: a ball thrown into a dark corner may be invisible to all the persons in a room at the same time; this is the same illustration of a lunar eclipse.

If the earth had no motion of rotation, the inhabitants of any one place would see something exactly resembling a lunar eclipse; the sun being in place of the moon, and the moon in place of the earth's shadow. But different places would see different kinds of eclipses, some losing more of the sun's body, and others less. The rotation of the earth, without materially altering the character of the phenomenon, makes it much more difficult to calculate: for it is as if each spot of the earth, instead of standing still to witness one phenomenon, or one simple eclipse, were constantly taking into view portions of different phenomena, a part of one followed by a subsequent part of another. In an eclipse of the moon, whatever may be the phase for the time being, from the disappearance of the first to the reappearance of the last edge, the only question as to whether such phase will be visible or not at any place is the following:—Will the moon be above the horizon at that place when the phase occurs? Suppose, for instance, it were asked, what places on the earth will see the beginning of the eclipse, the disappearance of one edge of the moon, at the instant when the moon rises? The answer is, calculate the absolute instant of the beginning of the eclipse, find out the spot to which the moon is vertical at that instant, and all places 90° distant from it will be exactly in the same predicament with respect to the eclipse. But in an eclipse of the sun, the beginning at two different places does not happen at the same instant; the inhabitants of any the same circle see very different phases, and a line drawn through all the places which see the same sort of phase under the same position of the luminaries with respect to their horizons, will be very different from a circle. Without attempting to give any account of the modes of ascertaining all these points, we subjoin, from the 'Nautical Almanac,' a projection of the eclipse which took place on the 7th of July, 1842.

The southern line passes through all the places which see a simple contact of the luminaries and nothing more: the edges of the luminaries unite for a moment and then separate. This line touches the two ends of a large figure of eight divided by another line passing through its loop; and the portion of the earth which at any time sees a total eclipse is contained in the broad shaded band. On the line marked "beginning of eclipse at sunrise" live those to whom the luminaries rise in contact: the other lines are similarly explained. The eclipse is first seen at the place marked "First contact" on the line just mentioned. One point is marked as having both beginning, middle, and end of the eclipse at sunrise: this means that the eclipse is there only a contact, so that its beginning, middle, and end take place at the same moment, and that moment is sunrise. At the loop of the figure of eight, the beginning, middle, and end are represented as each of them taking place both at sunrise and sunset: which must be a mystery to those who are not used to trace mathematical conceptions to their limits: are there two eclipses, one for sunrise and one for sunset? The explanation is this: there is at every moment of time a point in the arctic regions at which the sun is making its first appearance or its last appearance previously or subsequent to the long polar day or night. As this moment approaches the days shorten, if the disappearance be coming on, and begin from nothing if the appearance be coming on: the long day or night being preceded by the ordinary days or nights of the rest of the earth. Now the point which is at the loop is that point of the earth at which the sun and moon are in contact (without any further eclipse) at the moment when the sun first grazes their horizon after their polar night: so that their day is but a moment, and at that moment the contact takes place.

The figure of the projection is not always like that of the preceding: sometimes the loops become two ovals separated by a line which is continued through the middle of them, the part of this line between the ovals being a line on which nothing but a simple contact is seen.

There is an excellent mathematical account of eclipses in general, with the full mode of calculating them, and examples, by Mr. Woolhouse, in the Supplement to the 'Nautical Almanac' for 1836. From this we extract the summary of the limits within which an eclipse, whether of the sun or moon, can happen.

At the time of full moon an eclipse of the moon will be certain when the moon's latitude is less than $51' \, 57''$, impossible when it is greater than $63' \, 45''$, and doubtful between these limits. For the doubtful cases an eclipse will result when the moon's latitude is less than

$$\frac{61}{60}(p + \pi - \sigma) + s + 16''$$

p and s being the equatorial horizontal parallax and semi-diameter of the moon, and π and σ those of the sun.

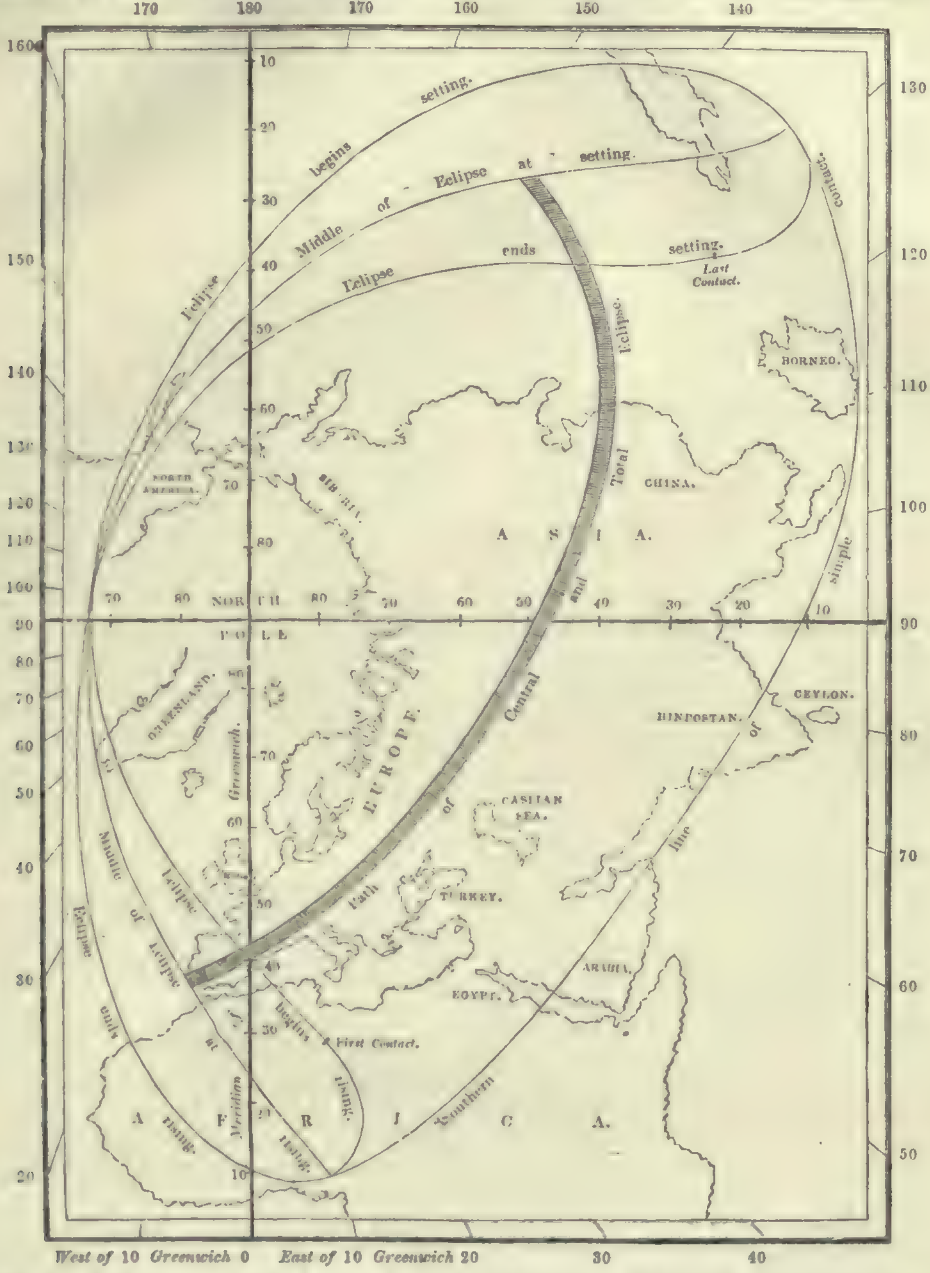
At the time of new moon an eclipse of the sun will be certain when the moon's latitude is less than $1^\circ \, 23' \, 15''$, impossible when it is greater than $1^\circ \, 34' \, 52''$, and doubtful between these limits. For the doubtful cases, an eclipse will happen when the moon's latitude is less than

$$p - \pi + \sigma + s + 25''.$$

It is hardly necessary to state that eclipses of the sun are frequently wholly partial, that is, not total for any one moment to any one part of the earth. Sometimes, though the eclipse be central, it is not total on account of the moon not being near enough to hide the whole of the sun; in which case part of the latter is seen as a bright ring round the part hidden by the moon, and the eclipse is called annular.

Before proceeding to give some account of the physical phenomena observed during total eclipses of the sun, it may be desirable to allude briefly to some of the more interesting eclipses of this nature recorded in history.

The ancient literature of Greece and Rome contains several incidental allusions to the occurrence of total eclipses of the sun. The most celebrated of these is the eclipse mentioned by Herodotus as having taken place during a battle between the Medes and Lydians. The historian relates that the two hostile armies were so much terrified by the spectacle of the eclipse, that they suddenly desisted from fighting, and concluded a treaty of amity and peace. He further states that the eclipse had been foretold to the Ionians by Thales the Milesian. The precise date of this eclipse has given rise to much discussion in modern times. In 1811 the late Francis Baily communicated a paper to the Royal Society, in which, by availing himself of Bürg's lunar tables, he endeavours to prove that a total eclipse of the sun which occurred on the 30th of September, 610 B.C., must have been the one alluded to by Herodotus. He acknowledges, however, that the elements of the lunar orbit employed in his investigation failed to account also for a total eclipse of the sun which Diodorus Siculus mentions as having occurred while Agathocles, king of Syracuse, was proceeding with his fleet to Africa. In a paper published in the 'Philosophical Transactions of the Royal Society' for 1852, Mr. Airy has taken up the subject of this eclipse. His researches are based upon a new determination of the elements of the lunar orbit derived from the Greenwich observations, and the values of the secular acceleration of the mean motion and node assigned by Professor Hansen. The conclusion at which he arrives is, that the eclipse referred to by Herodotus must have occurred on the 7th of September, 585 B.C. He shows that this date accords satisfactorily with the eclipse of Agathocles, and also with an eclipse briefly alluded to by Xenophon as having occurred at Larissa, in Asia, during the retreat of the ten thousand Greeks.



Path of the Moon's Shadow and Penumbra over the Surface of the Earth during the total Solar Eclipse of July 7, 1842.

Plutarch, in his 'Dissertation on the Lunar Spots,' makes a brief but interesting allusion to a total eclipse of the sun which happened in his time. He mentions that it occurred about midday, that the darkness was so great as to cause the day to resemble night, and that stars were everywhere visible. Kepler, who investigated the probable time of the occurrence of this eclipse, is of opinion that it is identical with an eclipse which happened in the year 113 A.D.

The records of modern history contain a variety of interesting allusions to the occurrence of total eclipses of the sun.

Halley, in a paper on the total eclipse of the sun which happened at London in the year 1715, mentions, as an illustration of the rarity of such phenomena, that no previous eclipse of the same nature had been visible in the metropolis since the year 1140. This eclipse is recorded in the Saxon Chronicle; a brief mention of it is also made by William of Malmesbury. In the Saxon Chronicle it is stated that, "in the Lent, the sun and the day darkened about the noontide of the day, when men were eating, and they did light their candles to eat by. That was the thirteenth day before the Calends of April. Men were very much struck with wonder." William of Malmesbury states, "that while persons were sitting at their meals, the darkness became so great that they feared the ancient chaos was about to return; and upon going out immediately, they perceived several stars about the sun."

Total eclipses of the sun are mentioned in history as having occurred in the years 1187, 1241, 1415, 1433, 1485, 1506, 1530, 1544, 1560, 1567, 1598, 1605, 1652, and 1699. The eclipses of 1433, 1598, and 1652 were visible in the British Isles. The eclipse of 1433 occurred in Scotland. According to Maclaurin, there is a manuscript account of it preserved in the library of the Edinburgh University. The moon's shadow on the occasion of the eclipse of 1598 appears to have passed over the border counties of England and Scotland. The day of its occurrence, which was Saturday, was long remembered in both countries as Black Saturday. The eclipse of 1562 was visible in the north of Ireland and in Scotland.

In 1706 there occurred a total eclipse of the sun, which was visible in the southern countries of Europe. At Montpellier, where it was observed by Plantade and Capiés, the total obscuration lasted $4^{m}\ 10^{s}$.

During this time, the dark body of the moon appeared to be surrounded by a corona of pale light. The planets Venus, Mercury, and Saturn, and several of the fixed stars, were visible to the naked eye. On the summits of some of the mountains of Switzerland, where the view was not impeded by the gross vapours which accumulate in the lower regions of the atmosphere, the stars appeared as thickly strewed as in the time of full moon.

On the 3rd of May, 1715, there occurred a total eclipse of the sun, which was visible in London, and of which Halley has given an interesting account in a paper published in the 'Philosophical Transactions of the Royal Society' for the same year. The total obscuration lasted $3^{m}\ 22^{s}$. The planets Jupiter, Mercury, and Venus, as well as Capella and Aldebaran, were visible to the naked eye.

On the 22nd of May, 1724, a total eclipse of the sun occurred at Paris. The total obscuration lasted only a little more than two minutes. Venus, Mercury, and a few of the fixed stars were visible to the naked eye.

The next total eclipse of the sun recorded in history was visible in the northern countries of Europe. It occurred on the 2nd of May, 1733. The total obscuration lasted a little more than three minutes. The planet Jupiter, the stars of Ursa Major, Capella, and several other stars, were visible to the naked eye. Besides the corona, several reddish patches of light were seen around the dark body of the moon. This is the earliest allusion to the well known red prominences which have excited so much interest in recent years.

A total eclipse of the sun which occurred in the Southern Ocean on the 9th of February, 1766, was observed by the persons on board the French ship the Comte d'Artois. The obscuration lasted only 5·3 seconds.

On the 24th of June, 1778, a total eclipse of the sun was observed at sea by the Spanish Admiral Don Antonio Ulloa, while proceeding from the Azores to Cape St. Vincent. The obscuration lasted four minutes. The corona around the moon appeared in great splendour.

On the 16th of June, 1806, a total eclipse of the sun was visible in North America, at Kinderhook, in the state of New York, where it was observed by Don Joachim Ferrers. The obscuration lasted $4^{m}\ 37^{s}$.

Another total eclipse of the sun, which was visible in America, occurred on the 30th of November, 1834. At Milledgeville, Georgia, where it was observed by the French astronomer Nicollet, the obscuration lasted $1^{m}\ 15^{s}$. At Beaufort, South Carolina, two planets and four stars of the first magnitude were visible to the naked eye.

On the 7th of July, 1842, there occurred a total eclipse of the sun, which was visible in the south of Europe. At Perpignan, where the phenomenon was observed by the late M. Arago and other French astronomers, the complete obscuration of the solar disc lasted only $2^{m}\ 24^{s}$. In the countries of Eastern Europe, the interval of totality was somewhat longer. At Lipesk, it lasted $3^{m}\ 5^{s}$. The corona on this occasion was very conspicuous. Several red protuberances were also seen around the dark body of the moon.

On the 8th of August, 1850, there occurred a total eclipse of the sun, which was visible in the islands of the Pacific Ocean. At Honolulu, the chief town of the Pacific Isles, it was observed by M. Kutczycki, who has given an interesting account of the phenomenon in the 'Comptes Rendus' of the Academy of Paris for April 21, 1851. The red prominences were very conspicuous on this occasion.

The next total eclipse of the sun occurred on the 28th of July, 1851, and, having been visible in the northern countries of Europe, was observed by a great number of astronomers. The totality, generally speaking, lasted about three minutes. Several rose-coloured prominences were seen around the moon's limb.

On the 30th of November, 1853, there occurred a total eclipse of the sun, which was visible in South America. At Occaje, in Peru, it was observed by M. Moesta, director of the National Observatory of Santiago, in Chili. The totality lasted $2^{m}\ 59^{s}$. The planets Jupiter and Venus were very conspicuous. Antares, which was within 5° of the sun, was also distinctly visible. Several rose-coloured prominences were observed around the moon's limb.

On the 7th of September, 1858, there occurred a total eclipse of the sun, which was also visible in South America. At Paranagua, in Brazil, it was observed by M. de Mello, director of the Imperial Observatory of Rio Janeiro; by M. Liais, a French astronomer; and several other individuals despatched for the purpose by the Brazilian government. Several protuberances were seen. The corona appears to have exhibited a very complicated structure. The planets Venus, Mercury, and Saturn, besides Sirius, Canopus, and three other stars, supposed to be α and β Centauri and α Crucis, were seen during the totality.

The last total eclipse of the sun which we have to mention is one which occurred on the 18th of July, 1860. On this occasion, the moon's shadow first traversed a portion of the North American Continent; it then swept across the Atlantic, and subsequently scoured the entire breadth of the Spanish peninsula, the eclipse terminating in the French colony of Algiers. The phenomena of the eclipse were observed by a great number of astronomers, both official and private, who had repaired to Spain for that purpose from every country in Europe. The British government placed at the disposal of the observers from this country the steamship Himalaya, for the purpose of conveying them from England to the Spanish coast. A party consisting of between forty and fifty individuals, headed by the Astronomer-Royal, availed themselves of this liberal offer. The greater number of the observers disembarked at Bilbao, a town in the Bay of Biscay; the remainder proceeded to Santander, which is situate about 30 miles further west. An arrangement was made by which the observers distributed themselves as widely as circumstances would admit over the track of the moon's shadow, with the view of guarding against casualties of the weather. A party, consisting of Captain Jacob, late director of the Madras Observatory, the Rev. Dr. McTaggart of Glasgow, and the writer of the supplementary matter of this article, observed the eclipse from the southern slope of the Sierra de Tolonio, a lofty mountain-range, commanding a most extensive view of the valley of the Ebro, along which the moon's shadow was to pass. The total obscuration of the solar disc lasted $3^{m}\ 20^{s}$. The planets Venus and Jupiter were seen shining with great splendour. Persons whose attention was not distracted by other matters perceived also seven or eight fixed stars. The corona was unusually brilliant on this occasion. Several rose-coloured protuberances were also visible.

We shall now give a special description of some of the more prominent features of total eclipses of the sun.

The corona of light which surrounds the dark body of the moon during the totality of a solar eclipse has been remarked by more than one ancient author. Plutarch especially refers to it in very explicit terms. Speaking of total eclipses of the sun he says:—"But even although the moon were at any time to conceal the whole body of the sun, still the eclipse is deficient in duration as well as amplitude, for there is seen around the margin a certain brightness which prevents the shadow from being very deep." All modern accounts of total eclipses of the sun agree in describing the corona as a characteristic feature of the totality. Its light has been generally remarked to be of a pale silvery colour, and to diminish gradually in brightness from the moon's limb. Its breadth may be said to amount to half the moon's radius, but there extend from it rays of much greater length, causing it to resemble the *glory* which painters in Roman Catholic countries throw around the heads of the saints.

Whatever may be the physical cause of the corona, it is very plain from the accounts of observers, that its brightness is not the same during every eclipse. Thus M. Kutczycki states, that on the occasion of the total eclipse of 1850, the corona vanished at the very instant of the reappearance of the solar light. A similar statement is made by M. Moesta with reference to the total eclipse of 1853. On the other hand, in the case of the eclipse of 1860, the writer distinctly perceived the corona at least ten seconds before the totality. Certain other observers perceived it even earlier. It also continued to be visible for several seconds after the reappearance of the solar light. In consequence of the bright light of the corona, the darkness during the totality was not so intense as it usually is during the occurrence of such phenomena.

We shall now advert briefly to the rose-coloured protuberances seen around the moon's dark limb during the totality of a solar eclipse. These phenomena were first distinctly seen during the total eclipse of 1733, but they do not seem to have excited any interest until the observation of similar phenomena on the occasion of the eclipse of 1842 attracted the attention of astronomers to the subject. The following is a description by M. Mauvais of the protuberances as observed by him at Perpignan during the last-mentioned eclipse.

"A few seconds after the total obscuration, while endeavouring to measure the breadth of the corona, I perceived a reddish point at the inferior limb of the moon, which, however, did not project sensibly beyond the limb. After an interval of fifty-six seconds had elapsed from the commencement of the totality, the reddish point to which I have referred, transformed itself into two protuberances, similar to two contiguous mountains, perfectly well defined. Their colour was not uniform. Upon their slopes were seen streaks of a deeper tint. I cannot give a more exact idea of their aspect than by comparing them to the peaks of the Alps illuminated by the setting sun and seen afar off. After the lapse of one minute and ten seconds from the commencement of the totality, a third mountain was perceived to the left of the two others. It exhibited the same aspect as far as regards colour. It was flanked by some smaller peaks, but all were perfectly well defined. While this third mountain was in the process of issuing forth, the first two continued all the while to increase. They finally attained a height of about 2′. The interval between the two groups appeared to embrace an arc of about 25° on the moon's limb. The most considerable group, apparently the most western, seemed to me to be a few degrees to the left of the lowest point of the moon's disc."

Francis Baily, who observed the eclipse from a station in the vicinity of Pavia, in Italy, remarks ('Mem. Ast. Soc.,' vol. xv.) that the protuberances resembled mountains of prodigious elevation. Their colour appeared red, tinged with lilac or purple, or rather their aspect suggested the colour of the peach blossom. According to M. Littrow, who observed the protuberances at Vienna, their aspect, which was first white, changed to rose colour, and then to violet, and afterwards passed in a reverse order through the same tints. M. Otto Struve, who observed the eclipse at Lipesk, remarks, in reference to the rose-coloured protuberances, that a very large part of the moon's disc was garnished with a similar reddish bordering.

The red prominences which appeared during the total eclipse of 1851 have been well described by the numerous skilled observers who proceeded to the countries of Northern Europe for the purpose of observing the phenomenon. According to Mr. Lassell, they were of a most brilliant lake colour, a splendid pink, quite defined and hard. Mr. Dawes remarked a bluntly triangular pink body *suspended*, as it were, in the corona, and the distance of which from the moon's limb was observed to increase as the moon continued to advance over the solar disc. The isolated patch of light was also seen by the greater number of the observers of the eclipse.

M. Moesta, who observed the eclipse of 1853, remarked on the same side of the corona, with a very conspicuous protuberance, two darker spots, of a form approaching to a square, in apparent contact with the moon's limb. They seemed to indicate an interruption of the corona, or rather two apertures through which the dark ground of the heavens was visible. Their height above the moon's limb was estimated to amount to 1′.

The protuberances which appeared during the total eclipse of 1860 resembled in their general features those observed on previous occasions. One of them appeared isolated from the moon's limb, but was seen to approach the latter as the moon advanced over the solar disk.

The question has been much discussed, whether the red prominences seen during a total eclipse of the sun belong to the sun or the moon. The observations of the total eclipse of 1842 seemed to indicate that they are appendages of the sun, for it was remarked by several of the observers, that the protuberances on the western limb of the moon gradually increased in magnitude as the moon advanced over the solar disc, while those on the eastern limb similarly diminished in size, consequences which would necessarily result from the protuberances being situate behind the dark body of the moon. This view of the origin of the protuberances was also strengthened by similar observations made during the eclipse of 1851; but it was established beyond all doubt by the observations of the eclipse of 1860. On the last-mentioned occasion it was remarked by several observers, that as the moon advanced over the solar disk, the protuberances on the eastern limb of the moon which first came into view, gradually diminished in size, while those on the western limb, which at the commencement of the totality were invisible, gradually increased in dimensions. This interesting circumstance has also been indicated by photographs of the protuberances taken by Mr. Warren De La Rue, and by the Italian astronomer Professor Secchi.

Besides the protuberances which form so conspicuous an object during the totality of an eclipse, there has been generally observed at the parts of the moon's limb where the solar light disappears, and again at the parts where it reappears, a long red streak of light, apparently of the same physical nature as the protuberances, and tending to support the opinion that the whole surface of the sun is enveloped in such a substance.

Attempts have been made to connect the rose-coloured protuberances with the solar spots, but the results of a careful comparison of the two classes of phenomena do not seem to indicate the existence of any physical relation between them. Other observers have endeavoured, but with no better success, to account for the protuberances by means of the faculæ of the solar disk.

The most probable view of the nature of the more important phenomena which reveal themselves during a total eclipse of the sun, is that the corona represents an atmosphere about the sun, and that the protuberances are emanations from a substance enveloping the surface of the sun, and somehow connected with the generation of the solar light and heat.

We shall conclude this article with adverting briefly to a phenomenon, apparently originating in an optical delusion, which has been sometimes remarked on the occasion of total or annular eclipses of the sun. In the case of an annular eclipse, the western limb of the moon, previous to the formation of the annulus, exhibits an indented appearance, resembling a succession of beads. Almost immediately the beads become elongated, assuming the aspect of long black parallel streaks, uniting the limbs of the sun and moon. In the next instant these lines give way, as if they had been snapped asunder by the eastward motion of the moon, and the annulus then appears completely formed. The same succession of appearances has been witnessed when the eastern limb of the moon is approaching the corresponding limb of the sun. Phenomena of this nature were witnessed during the eclipses of 1724, 1737, 1748, and 1791. Nicolai also observed a similar appearance very distinctly during his observation of the annular eclipse of September 7, 1820, at Manheim. He remarked that about a second before the annulus was formed, the fine curve of the moon's disk, then in contact with the sun's limb, appeared broken into several parts; and in a moment these parts flowed together like drops of water or quicksilver near each other. De Zach, who observed the same eclipse at Bologna, also remarks that before the contact of the two limbs was effected, there was visible, not a continuous thread of light, but a number of luminous points, resembling a row of so many pearl beads, separated by dark intervals. But the most vivid description of the phenomenon has been given by Francis Baily, who observed the annular eclipse of May 15, 1836, at Jedburgh, in the south of Scotland. ('Mem. Ast. Soc.,' vol. x.) When the cusps of the sun, previous to the formation of the annulus, were about 40° asunder, a row of lucid points, like a string of beads, irregular in size and distance from each other, suddenly formed round the part of the circumference of the moon that was about to enter on the sun's disk. Its formation was so rapid that it presented the appearance of having been caused by the ignition of a fine train of gunpowder. His impression was, that the annulus had just been formed, but to his great surprise he found that the luminous points, as well as the dark intervening spaces, increased in magnitude, some of the contiguous ones appearing to run into each other, like drops of water; for the rapidity of the change was so great, and the singularity of the appearance so fascinating and attractive, that the mind was for the moment distracted, and lost in the contemplation of the scene, so as to be unable to attend to every minute occurrence. Finally, as the moon pursued her course, the dark intervening spaces (which at their origin had the appearance of lunar mountains in high relief, and which still continued attached to the sun's border) were stretched out into long, black, thick, parallel lines, joining the limbs of the sun and moon, when all at once they suddenly gave way, and left the circumference of the sun and moon in those points, as in the rest, comparatively smooth and circular; and the moon perceptibly advanced on the face of the sun. The same appearance, although in a reverse order, was witnessed on the breaking up of the annulus. While the limb of the moon was yet at some distance from the margin of the solar disk, a number of long, black, thick, parallel lines suddenly darted forward from the moon, and joined the two limbs as before. As these dark lines got shorter, the intervening bright parts assumed a more circular and irregular shape, and at length terminated in a fine curved line of bright beads, as at the commencement, till they ultimately vanished, and the annulus ceased to exist.

The phenomenon alluded to in the foregoing description, which has received the appellation of "Baily's beads," has been carefully sought for on the occasion of all the total and annular eclipses which have been observed in recent times, but no confirmation of its existence has been obtained except in a few doubtful instances. The most probable explanation of its origin is that which supposes it to be due to some imperfection connected with the optical qualities of the telescope.

SOLAR SYSTEM. We have given the elements of the planetary motions minutely in the several articles MERCURY, VENUS, &c., together with such physical peculiarities as belong to them severally, and independently of the System; the general phenomena of their motions have been deduced from the great principle of GRAVITATION; their history, as far as it is in the plan of this work to give it, has been treated in ASTRONOMY. It remains to bring together the dimensions of the various parts of the System, and to notice such points as could not properly find a place under any of the heads just mentioned.

By the Solar System is meant that collection of bodies which contains the Sun, the planets which revolve round him, their satellites, and such periodic comets as have had their returns successfully predicted. The system of the ancients includes the Earth as a fixed centre, with the Moon, Mercury, Venus, the Sun, Mars, Jupiter, and Saturn. That of the moderns includes at this day the Sun as a governing body (but not as a fixed centre), Mercury, Venus, the Earth (with the Moon), Mars, the group of minor planets (now amounting to sixty-four),* Jupiter and four satellites, Saturn (with his triple ring) and eight satellites, Uranus with four satellites, and Neptune with one satellite, besides a considerable number of periodic comets. The following symbols are used to represent the ancient members of the system, to which we add the received explanation, without expressing any opinion about it :—

☉ Sun.
☿ Mercury.
♀ Venus.
⊖ or ♁ Earth (modern).
☽ Moon.
♂ Mars.
♃ Jupiter.
♄ Saturn.

The symbol for the Sun is all that modern abridgment has left of a face surrounded by rays; Mercury has the caduceus, or rod, entwined by two serpents; Venus, a circular looking-glass with a handle; the Earth (a modern symbol) has a sphere with an equator, and also (with some) an inverted symbol of Venus. Those who first used it did not, we presume, know that they might be making a looking-glass turned upside down represent their planet. The symbol of the Moon is obvious; Mars has what remains of a spear and shield; Jupiter, supposed to be a symbol of the thunder (arm and hand holding thunder?); Saturn, an altered form of a mower's scythe, the emblem of time. But others have thought that Mercury was designated by putting σ and τ together, the initials of *στίλβων*; Venus, from the first and last letters of *Φωσφόρος*; Jupiter, from the first and last letters of *Ζεὺς*. These signs are found on very old manuscripts and gems, variously figured, but all with some general resemblance to the modern printed forms.

The four minor planets discovered about the beginning of the present century were also designated by symbols. Vesta had for its symbol ⚶, or an altar with fire on it; Juno was designated by a sceptre, ⚵; Ceres, by a reaper's scythe, ⚳; and Pallas by the head of a lance,

---

* Since the article ASTEROIDS was written, eight additional members of the minor planet-group have been discovered, namely :—in 1859, Mnemosyne, at Bilk, by Luther; in 1860, Concordia, at Bilk, by Luther; planet 59, name unknown, at Paris, by Chacornac; Danaë, at Paris, by Goldschmidt; Titania, at Washington, by Ferguson; Erato, at Berlin, by Förster; in 1861, planet 63, at Naples, by De Gasparis; planet 64, at Marseille, by M. Tempel. The total number of asteroids accordingly now (March, 1861) amounts to sixty-four.

⚳. This mode of designation has recently been abandoned. It is now usual to distinguish the asteroids merely by a number, enclosed in a circle, indicating their place in the order of discovery.

Uranus has been distinguished by the initial letter of Herschel's name, with the symbol of a planet attached, ♅; Neptune has for its symbol a trident, ♆.

We are now to state the relative dimensions of the Solar System in a rough manner. This, we think, it may be useful to do in such a manner that any two planets may be compared with one another without computation. The planet Ceres is used to represent the group of minor planets.

And first, as to the relative distances from the Sun, we have the following table :—

☿	100	54	39	25	15	74	41	20	14
♀	187	100	72	47	26	139	76	38	24
⊖	258	138	100	66	36	192	105	52	34
♂	394	211	152	100	55	293	160	79	52
⚳	715	382	277	182	100	532	290	144	95
♃	1344	719	520	341	187	1000	545	271	176
♄	2464	1319	954	626	347	1833	1000	497	323
♅	4955	2652	1918	1259	690	3686	2010	1000	649
♆	7740	4140	3002	1980	1086	5760	3150	1560	1000

This table represents the comparative mean distances of the planets from the Sun. In each column one of the distances is made 100 or 1000, and the rest are expressed accordingly. Thus we see by inspection that Uranus is about 12½ times as far from the Sun as Mars; about 19 times as far as the Earth; about 26½ times as far as Venus; and about 7¼ times the mean distance of the four small planets. Also, taking the mean distance of the small planets, we see that the distances from the Sun are as the numbers 15, 26, 36, 55, 100, 187, 347, 690; and if we take the first away from all the rest, we have 11, 21, 40, 85, 172, 332, 675, 1071, in which it will be observed that each is about double of the preceding, except in the case of the last two numbers. Kepler had observed a progression, without assigning a law, and had also noticed that one term appeared to be missing. Bode assigned the law which has just been noticed, noticing also the apparently missing term. The existence of a planet between Mars and Jupiter was accordingly suspected; and at last, to the astonishment of astronomers, four little bodies, looking more like fragments of a planet than planets, were discovered at a distance from the Sun so near to that which had been suspected, that their mean distance fills up its place in the series as well as that of any other planet. It was of course immediately suspected (when only two had been discovered) that these were remains of some planet which had been shattered by explosion or other cause; and the encouragement which this idea gave to look for further fragments, was perhaps one of the main causes of the discovery of the remaining two. It has been already stated that the number of bodies constituting the group of minor planets now amounts to sixty-four. This law of Bode, as it has been called from the astronomer who first noticed it, may be thus expressed: if a be the distance of Mercury, and $a+b$ of Venus, then $a+2b$ is that of the Earth, $a+4b$ of Mars, $a+8b$ of the small planets, $a+16b$ of Jupiter, $a+32b$ of Saturn, and $a+64b$ of Uranus. The law fails, however, in the case of Neptune, the distance of which is $a+99b$, instead of $a+128b$.

To convert the above relative distances into actual ones, consider the distance from the Sun to the Earth as 23,984 mean semidiameters of the Earth, the mean semidiameter being 3956 miles; so that the distance in question is 95 millions of miles. The semidiameter of the sun is 111·454 times that of the earth; so that the distance of the Earth from the Sun may be called 215 semidiameters of the Sun. One of our objects in this article is to correct the absurd notions derived from the playthings called orreries, and the diagrams exhibited in books and lectures. Let the capital letter O of the type which stands at the beginning of the article in this work represent the Sun; then the Earth is a speck which would need a good microscope to show it; and its distance from the Sun is represented by 11 inches, or nearly two inches more than the length of one of our columns. Sir John Herschel describes the Solar System thus :—

Planet.	Object which represents it.	Representative of its distance from the Sun.
Sun.	Globe of 4 feet diameter.	
Mercury.	Grain of mustard seed.	164 feet.
Venus.	A pea.	284 feet.
Earth.	A pea.	430 feet.
Mars.	A rather large pin's head.	654 feet.
Ceres, &c.	Grains of sand.	1000 to 1200 feet.
Jupiter.	A moderate sized orange.	Half a mile.
Saturn.	A small orange.	⅘ of a mile.
Uranus.	A full sized cherry, or small plum.	A mile and a half.
Neptune.	A good sized plum.	Two miles and a half.

The *excentricity* of a planet means the fractional part of a planet's mean distance by which its greatest or least distance exceeds or falls short of the mean distance. Arranging the larger planets in the order of their excentricities, we have

For Venus .	·007	For Uranus .	·047	For Mars .	·093
„ Neptune	·009	„ Jupiter .	·048	„ Mercury	·206
„ Earth .	·017	„ Saturn .	·056		

That is, if the mean distance of Venus were called 1000, its greatest distance would be only 1007, and its least 993.

For the excentricities of the minor planets, see Asteroids.

We now give a table for the times of revolution, similar to that given for the distances :—

☿	100	39	24	13	6	20	8	3	2
♀	255	100	62	33	14	52	21	7	4
⊖	415	163	100	53	21	84	35	12	6
♂	781	306	188	100	42	159	65	22	11
⚳	1911	748	460	245	100	388	160	55	22
♃	4925	1929	1186	631	257	1000	412	141	66
♄	11950	4680	2878	1531	624	2428	1000	343	163
♅	34880	13660	8401	4467	1824	7082	2918	1000	489
♆	68060	26732	16400	8692	3524	13776	5740	1968	1000

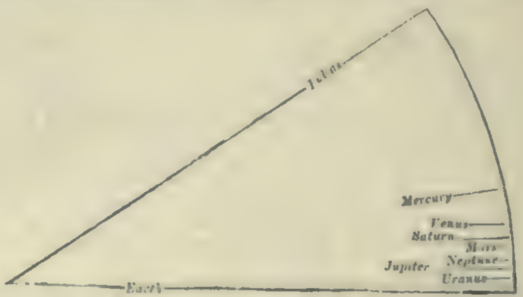
The explanation of this table resembles that of the preceding one—times, instead of distances, being the objects of comparison. Thus, if a revolution of Jupiter contain 1000 parts of time, that of Saturn has 2428 such parts; and the revolution of Uranus is 84·01 as long as that of the Earth.

In the following table will be seen the absolute time of revolution in days of each planet, and also numbers expressive of the intervals (in days) between two successive conjunctions with the Sun :—

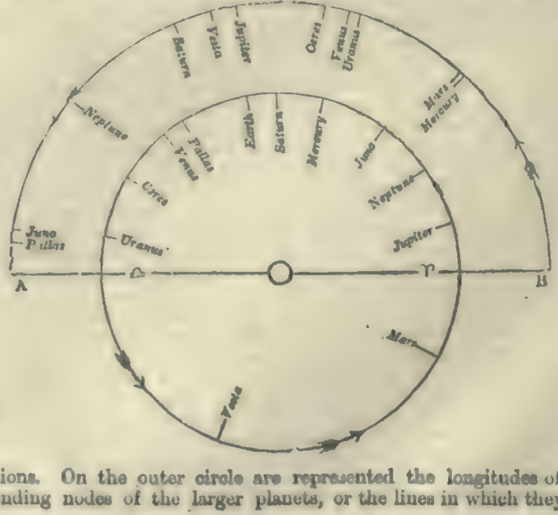
	Rev.	Int. of Conj.		Rev.	Int. of Conj.		Rev.	Int. of Conj.
☿	88	116	♂	687	780	♄	10759	378
♀	225	584	⚳	1681	467	♅	30687	370
⊖	365	—	♃	4333	399	♆	59860	368

Thus, Venus revolves in 225 days (all the numbers in this article are more roughly given than in the articles specially devoted to the planets); is in conjunction with the Sun at intervals of 584 days; and, with its mean motion, would describe 274° in the heavens while Jupiter describes 23°·1. Saturn moves 2·01 minutes daily; the Earth, 59′ 8″·3.

The minor elements (in a general consideration) may be best described by diagrams; the inclinations of the orbits may be represented by the following lines, which show the slope or inclination of each orbit to the orbit of the Earth or plane of the ecliptic. None of the old planets have an inclination of more than 7°, while in the new planets the same element varies from 40′ (Massilia) to 35° (Pallas).



In the next figure the plane of the ecliptic is represented: A B is the line which points to the astronomical first point of Aries, or the vernal equinox, and the arrows represent the directions of the planetary



motions. On the outer circle are represented the longitudes of the ascending nodes of the larger planets, or the lines in which they are found when they rise through the ecliptic from the southern to the northern side of it. On the inner circle are represented the longitudes of their perihelia, or points of nearest approach to the Sun. The slow changes which take place in these elements are noted in the articles devoted to the different planets.

A general view of the elements of the minor planets has already been given. [ASTEROIDS.]

Jupiter and his satellites might be inclosed in a sphere having a radius of about 2½ times as great as that of the Sun; Saturn and his satellites in a sphere of 7¾ the radius of the Sun; Uranus and his satellites in a sphere of 4½ the radius of the Sun; and Neptune and his satellite in a sphere of which the radius is a little greater than the Sun's radius. The Earth and Moon [MOON] might be contained in a sphere of one-half the radius of the Sun.

In apparent diameter Mercury varies from 5″ to 12″; Venus from 10″ to 61″; Mars from 4″ to 18″; the small planets have diameters hardly measurable; Jupiter from 30″ to 46″; Saturn from 14″ to 18″; Uranus from a little less to a little greater than 4″; Neptune oscillates about 3″.

If the radius of the Sun were divided into 1000 parts, there would be as follows in the radii of the several planets:—Mercury, 3½; Venus, 8¾; the Earth, 9; Mars, 4⅞; Jupiter, 97½; Saturn, 85; and Uranus, 39. If the bulk of the Sun were divided into a *million* of parts, Mercury would be a little less than one-twentieth of one of the parts; Venus, two-thirds of a part; the Earth, three-quarters of a part; Mars, one-tenth of a part; Jupiter, 925 parts; Saturn, 720 parts; Uranus, 58 parts; Neptune, 120 parts. The Moon is about the third part of Mercury in bulk.

The masses of the planets vary very much from what they would be if they were nearly of the same substance. From the effects of the planets in attracting their satellites, compared with the effects of the Sun upon themselves, it is found that if, according to Cavendish's experiment, we take the Earth to be, at a mean, 5½ times the density of water, or about half that of lead, the Sun may be considered, as to density, to be made of asphaltum, or rather heavy coal; Jupiter, of the same; Uranus and Neptune, each of a material very little heavier; Saturn, of maple-wood; the Moon, of diamond or topaz. By other modes, of course, than that of their satellites, Mercury is found to be three times as dense as the Earth; Venus, of about the same density; and Mars, about three-quarters as dense as the Earth.

The Sun revolves about its axis in about 25½ sidereal days; Mercury, Venus, the Earth, and Mars, all revolve in about the same time, from 23½ʰ to 24½ʰ; Jupiter and Saturn severally revolve in about 10ʰ and 10½ʰ. About Uranus and Neptune, nothing is known in this respect.

From what precedes, a sufficient general notion may be collected of the dimensions of the Solar System, and we now proceed to some other points connected with it. As to its place among the fixed stars, it is only within the last twenty years that the distance of any star from our system may be said to have been positively measured. [PARALLAX OF THE FIXED STARS.] The star 61 Cygni is shown to be more than 340,000 times as far from our system as its most distant discovered planet is from the Sun. As to the question of the motion of the Solar System in space, consult the article which follows.

The next question may be, is there any evidence in our System of any secondary law of formation, indicating a connection between the mode of creation of one planet and another? The will and power of the Creator are the final causes both of the initiation and maintenance of this vast machine; but in the latter there are visible secondary laws, that of attraction, for instance: were there any in the former? Attempts at investigation on this point have been frequently considered atheistical; a foolish notion, arising out of those views to which we have alluded in MOTION. Those who can only think of the *Creator* and forget the *Maintainer*, and who virtually separate the office of the latter, and give it to the "laws of nature," may reasonably fear that they would have to give up also the former office to the "laws of creation," if such were found; which would be (but owing only to their own interpretation of the manner in which the world *continues* to exist) a renunciation of the idea of Deity in the contemplation of the manner in which it *began* to exist. But to those who keep constantly in view the fact which no modern theist disputes, that the same power which created continues to create in preserving, and that the "laws of nature" are only expressions of the manner in which this preservation is seen to act, will look upon the "laws of creation" to be as simple and natural an object of philosophical inquiry as those of the ascent of sap in a plant, or of the revolution of a planet. The proper reply to a charge of atheism brought against those who investigate any mode of action of the Creator of the universe, at any *past* time, is the retort of semi-atheism against those who make it.

Many speculations have been made upon the formation of the several planets, but none which has any appearance of connecting the phenomena of one planet with those of another, except by Laplace ('Système du Monde,' vol. ii., note 7), in what has been called the nebular hypothesis. This conjectural theory, which is well worthy of attention, never received any particular notice, to our knowledge, from any writer in this country, until Mr. Whewell's 'Astronomy and General Physics,' the third of the Bridgewater Treatises, appeared, in which it is announced that the nebular theory was ushered in with expressions which showed Laplace to be a professor of atheism. What Laplace really thought on these subjects, as we have said before [LAPLACE, in BIOG. DIV.] we do not know, nor would it really matter if he were what he was represented to have been; for a conjecture may be ingenious, and a theory sound in its details, even though its author made it stand in the place of a Creator. But considering the collateral associations connected with such a charge, it will be well to examine into the fact whether there was any such announcement; and to do this fairly, we must quote both Mr. Whewell and Laplace. The former says, "We have referred to Laplace as a profound mathematician, who has strongly expressed the opinion that the arrangement by which the stability of the Solar System is secured is not the work of chance; that 'a *primitive cause* has directed the planetary motions.' This author, however, having arrived, as we have done, at this conviction, does not draw from it the conclusion which has appeared to us so irresistible, that 'the admirable arrangement of the Solar System cannot but be the work of an intelligent and most powerful Being.' He quotes these expressions, which are those of Newton, and points at them as instances where that great philosopher had deviated from the method of true philosophy. He himself proposes an hypothesis concerning the nature of the *primitive cause,* of which he conceives the existence to be thus probable."

Here are two assertions:—1. That it is the doctrine of an intelligent Creator which Laplace "points at" as a deviation from true philosophy; 2. That Laplace proposes his nebular hypothesis as a primitive cause. We pay a writer of Mr. Whewell's character the compliment of inserting here matter which would more appropriately appear in a review of his work: and we deny that Laplace has been well described in either assertion. Our object is to clear the nebular hypothesis from the unphilosophical character with which its first appearance is thus presented, and by no means to uphold the moral dignity of Laplace. Until the biting facts connected with his treatment of his benefactor are answered or explained, that great mathematician must be called a time-server; and we suspect that his 'Système du Monde' only treats the intelligent Creator whom his mind acknowledged in the same manner as he afterwards treated Napoleon. It was published in 1796, a period which would well explain the mere suppression of all allusion to the Supreme Being: and one of these things must be true; either Laplace was what Mr. Whewell styles him, or he had not the courage to declare himself otherwise in his age and country. But what we have here to do with is the assertion that he did more—that he *attacked* the doctrine of a Supreme Being. His words are as follows, the passages to which we wish to draw attention being in Italics:—"I cannot here help observing how much Newton has departed on this point from the method which he elsewhere so happily applied. After the publication of his discoveries, this great geometer, abandoning himself to speculations of another nature, *inquired into the motives which made the Author of nature give to the solar system* the constitution which we have described." Laplace then quotes Newton's Scholium [PRINCIPIA, cols. 742–743, where we have translated the whole] thus: "*And all these regular motions have no origin in mechanical causes,*"[*] &c., &c., down to "all parts of the heavens." He then further quotes, "This most elegant group, &c., can only arise from the design and government of a powerful and intelligent Being." He (Laplace) continues thus, speaking, so far as the mere notion of a Supreme Being is concerned, rather in approbation: "He repeats the same thought at the end of his 'Optics,' in which he would have been still more confirmed if he had known what I have demonstrated, namely, that the arrangement of the planets and satellites is precisely that which makes a certain provision for their stability. 'Blind destiny,' says Newton, 'can never make the planets move thus with such small irregularities, which appear to come from the mutual action of the planets and comets, *and which will probably become greater and greater in the course of time, until at last the system will again require its Author to put it in order.*' But," proceeds Laplace, "may not this arrangement of the planets be itself a consequence of the laws of motion? and may not the Supreme Intelligence, which Newton makes *to interfere,* have already made it depend upon a more general law? *Are we to affirm that the* [unlimited] *preservation of the Solar System is a part of the intentions of the Author of Nature?*" This we should sum up as follows:—Laplace charges Newton with a departure from philosophical principles in—1, speculating on the motives of the Creator;[†] 2, assuming the probability that his works would not last his time without his own supernatural interference; 3, assuming that he intended to preserve the Solar System for ever. But Mr. Whewell singles out only one part of Laplace's quotation, and, without paying any attention to the remarks which explain his meaning, declares that Laplace "pointed at" Newton's declaration of belief in God as a piece of bad philosophy; whereas this part of his quotation is only followed by the remark how much stronger he himself (Laplace) had been able to make the sort of evidence on which Newton rested; and the sentence selected by Mr. Whewell as "pointed at," coupled with the remark specially made on that sentence, has rather the appearance of being pointed at with approbation. With regard to the assertion that Laplace propounded the nebular theory as a *primitive cause*, it is true that he did so in his own sense of the words. Mr. Whewell means by primitive cause a first cause, as those words are usually understood; and he asks (and the question would have been much to the purpose if Laplace had really meant the same thing as himself by the words *primitive cause*), "Was man, with his thought and feeling, his powers and hopes, his will and conscience, also produced as an ultimate result of the condensation of the solar atmosphere?" But Laplace speaks as follows:—"Quelle est cette *cause primitive?* J'exposerai sur cela, dans la note qui termine cette ouvrage, une hypothèse," &c. And in the very first words of this note we find, "On a, pour remonter à la *cause* des mouvemens *primitifs* du système planetaire," &c. This then is what Laplace understood by *primitive cause*, a *cause* of the *primitive* motions;—an improper use of language, if the reader pleases; but when a man puts his own meaning on his own words, no one has a right to fix the consequences of another meaning upon him.

---

[*] Laplace evidently thought that by mechanical causes Newton meant what we now call second causes. See the reference just made.

[†] Newton's Scholium does not seem to us to do any such thing; but that is not the question. Laplace's approval or disapproval is of course to be applied to his own interpretation of Newton's meaning, not to ours.

We now proceed to the nebular theory, which is a conjecture proposed with much doubt by Laplace, as a possible explanation of the manner in which the *motions* of the several planets obtained those remarkable resemblances which are found to subsist, without making the inquiry extend to anything except their motions. All the planets move in one direction round the sun, and their satellites move in the same direction round themselves; those that are known to revolve round their axes (and the contrary has been proved of no one of them) also revolve in the same direction, and their equators are not much inclined to their orbits. The excentricities of the planets and satellites are in no case very large, and generally very small; and the inclinations of their orbits to one another are generally small. Many nebulæ in the heavens appear, when examined, to consist of a bright nucleus surrounded by nebulous matter; in others it is found that the apparently nebulous matter consists of stars. This gave Laplace the idea that our System might originally—that is, previously to the establishment of its present order—have been a large nebula, of which the sun was at the centre. Imagine a large nebulous mass in a state of revolution, with a solid, or at least less nebulous, centre, round which it revolves: call this central nucleus the sun. Assume the ordinary laws of matter to be true of this nebulous mass; and also that it extends as far as such an atmosphere can do—namely, until the attraction of the whole upon particles at the equator is equal to the centrifugal force of those particles. If condensation should begin to take place, arising from loss of heat, the mass would revolve more and more rapidly as it was condensed into less and less space; but it does not follow that the equatorial particles would fall in towards the centre: they are balanced by the equality of the centripetal and centrifugal forces, and might form a ring round the rest of the mass. If the process were conducted with great regularity, this ring and the mass of vapour might undergo continual condensation together, until the increasing velocity of rotation prevented the formation of the ring from continuing. The departures from complete regularity which might exist in the mass might cause disturbances in the formation of the rings, which might end in there being one or more (not many) permanently revolving round the rest of the mass condensed into a solid body, in the manner of Saturn and its rings. Such regular formation, however, might be rarely continued long enough; and if the rings got broken, each ring would become several masses, which would revolve nearly at the same distance, and nearly with the same velocity: such a result is seen in the four small planets. But as, generally speaking, these masses would, by irregularities in their velocities, be combined into one [*] at last, each broken ring would form a new nebulous mass, revolving round the diminished central nucleus; and if a number of such masses were formed, those nearer to the central mass would move with the greater velocity, and would be both smaller and denser than the external ones: the first circumstance certainly, the second and third most probably. Again, each mass would have a motion of revolution in the same direction [Motion, Direction of] as the motion round the primary; for when the ring becomes broken, its internal parts have a somewhat more rapid motion than the external ones, which would give the motion of rotation noticed. And the rotations thus created in the internal masses would probably be greater than those in the external masses. The orbits of the masses would necessarily be nearly circular, and not much inclined to each other; but for irregularities, quite circular, and in the same plane. In each of the nebulous masses thus detached and revolving, condensation might again give rings or satellites, or both; but in all probability the external masses would get more satellites than the internal ones: the orbits of the satellites must be also nearly circular, and not much inclined. All the preceding circumstances, both those which are certain and those which are probable (Laplace confined himself to the former), are actually existing in the Solar System; consequently this hypothesis, though subject to serious difficulties, deserves attentive consideration, as often as any new knowledge of the constituent parts of our system shall render a reference to it likely to produce evidence on one side or the other. As a substitute for intelligent creative power, if such a thing were intended, it would do no better than any other; for, as Mr. Whewell observes, a man with will, power, and conscience, cannot be admitted to be a necessary consequence of the cooling of a nebulous atmosphere. Nevertheless, as exhibiting a possible mode in which the Creator of mind and matter made the laws of formation resemble those of continuation, as far as the motions of the system are concerned, this hypothesis is strikingly explicative of what we really see. But even if we were to take it to be a true explanation, it would only be one step of the ascent, and the next question would be, what higher process distributed the parts of this nebulous mass in such a manner as to place those outermost which were fit to form a planet so distant from the source of light and heat as Neptune, and to support the appropriate forms of animal and vegetable life which analogy would induce us to suppose must exist there.

The history of astronomy teaches us that the system in which we live has not undergone any apparent change for more than 2000 years; and, on inquiring into the connection which exists between one planet and another, or the laws of gravitation, it is found that so far as their mutual actions are concerned, there is no reason why any change ever should take place. If the central body were the only one which attracted the rest, and as long as the laws of matter remained unaltered, it is certain that nothing could alter the revolutions of a system of planets, unless two orbits intersected, and the planets of those orbits happened to come to the intersecting part at the same time, and to strike each other. But the planets are subject to the action of each other as well as to that of the sun, and no instant elapses without every orbit undergoing a slight change from every one of the planets of the other orbits. Jupiter alone produces on the earth's orbit in one year more change than we have any right to say all the comets put together would do in a hundred. And yet the system not only continues without any sensible change, but, one circumstance alone excepted, to which we shall presently allude, is demonstrably formed to continue for a most enormous length of time, unless some new action should arise, or some external cause begin to operate. As it is sometimes stated that a complete mathematical demonstration has been given of the *eternal* stability of the Solar System, so far as the mutual actions of its parts are concerned—an assertion which is altogether incorrect—it may be worth while to enter a little on the details of this subject.

The disturbing forces of the planets on each other cannot have their effects calculated all at once; but each force must be divided into an infinite series of terms, the first of which contains all the terms of the first dimension, the second all those of the second, and so on. Of all these terms each is much less in its effect than the preceding; so that in fact the first two dimensions are all that produce any sensible effect in any time which it is worth while to consider. Occasionally it happens that terms of the third and fourth dimensions have been required to be used, but almost all the sensible perturbations of the system depend on terms of the first two orders. As far as any effects arising from such terms are concerned, Lagrange and Poisson are admitted on all hands to have demonstrated the stability of the Solar System: and considering the nature of the process employed, and there being no appearance of any circumstance which looks likely to lead to a different result in any of the remaining terms of the disturbing forces, it may be highly probable that a further investigation would show the same thing, if all the dimensions of the disturbing forces were employed. Sir J. Lubbock ('Phil. Mag.,' February, 1831) has pointed out the forms which further investigation would apparently produce, and which would (unless a detailed investigation should lead to something not discoverable *à priori*) bear out as certain what we have just stated to be probable. But though all the presumptions lie on the side of those who would assert the proposition absolutely of all dimensions of the disturbing force, it is not yet time to say that it is a certain mathematical consequence of the theory of gravitation.

When the effects of perturbation are examined, as far as the second dimension of the disturbing force, it appears that the immense mass of the sun compared with that of any planet, the great distance of the planets from each other as compared with their amounts of departure from spherical form, the small excentricities and inclinations of their orbits, and their motions being all in one direction, give the following mathematical consequences of the law of attraction:—First, the longest or major axes of the planets' orbits are not subject to any slow variations of very long period; all their variations being excessively small, and soon destroyed by the production of contrary variations. It is very often stated that the major axes are subject to no variation; this is to be understood only of *secular* variation (or of a very long period). One year is not precisely the same as another to any fraction of a second; but the average year of one long period *is* precisely the same as that of another; or at least the mean years of the two periods become more nearly equal the longer the periods are made. But the excentricities and inclinations are subject to long periodic alterations, the times of their recurrences not being exactly settled, from the difficulty of their determination. How then is it known that they are periodic? For instance, the excentricity of the Earth's orbit is subject to a yearly diminution of ·00004, its value in 1801 being ·017. Had this diminution been an increase, as it is in Mercury and Jupiter, it might *à priori* appear possible that this increase should continue until the orbit (preserving the same major axis) should be so elongated that the ultimate approach to and recession from the sun should give our planet the alternate climates of Mercury and Mars, and thus no doubt destroy it as the abode of beings constituted like ourselves. It is found, however, that the following relation must exist :—If at any one moment the square of the excentricity of each planet be multiplied by its mass and the square root of its mean distance from the sun (represented in numbers), the sum of all these products must be the same as it was at any moment past, or will be at any moment future. And if in each product the tangent of the inclination to a fixed plane be substituted for the excentricity, the resulting equation is true. From such relations as these, and others connected with them, it is shown that so far as the mutual actions of the planets are concerned, no one excentricity nor inclination can increase indefinitely, but all their changes must be periodic, and confined within rather small limits. The approach of the ecliptic to the equator, for instance, which amounts to about half a second in a year (and which leads speculators sometimes to talk about a past time when the ecliptic passed through the pole, and a future time when it will coincide with the equator), must stop long before the ecliptic reaches the equator, and attain a minimum inclination, after which the two will begin to separate; the whole oscillation being less than three degrees. The whole result is summed up thus: As far as terms of the second order (inclusive) in the disturbing forces, and as long as only the mutual attractions of the planets act, there is a mathematical certainty that the Solar System will remain in its present state, the elements of the different orbits oscillating about certain mean values, from which they are never very distant : except only the longitudes of the nodes and perihelia, which change with velocities which are always very near to certain mean velocities. The probability is very small that the higher dimensions of the disturbing forces would affect this result, and certainly only in a length of time to which the longest periods known are trifling in comparison.

---

[*] If any number of masses, capable of cohering, revolve in orbits so near to one another, that they must cohere when they come to their minimum distance, nothing but an absolute and mathematical equality in their mean velocities can keep them permanently asunder; the smallest inequality must at last bring them all together.

This last point, however, is of the less importance, since it has become highly probable, within the last few years, that an external cause does exist, which must, unless there be a counteracting force of which we know nothing, in time cause the destruction of the System. If the planets move in any medium which resists their motions, however little, the consequence must be a gradual diminution of their mean distances from the sun, and a gradual increase of their velocities, ending in their absolutely falling into the sun. For the presumption in favour of the actual existence of such a resisting medium, see COMET. This retarding agent seems to show a rapid effect upon so attenuated a mass as Encke's comet, though thousands of years have elapsed without its producing any sensible effect upon the planets. Little as it may concern us directly, these speculations have an interest, both as to the glimpse they give of the possible destiny of our System, and from their association with the history of past and the hope of future discovery. It is to be remembered that no science has drawn out so much of mathematical talent, or indirectly excited such an influence upon other branches of physical research, as the application of the theory of gravitation to the development of the planetary motions.

SOLAR SYSTEM, MOTION OF THE, IN SPACE. One of the most interesting results of modern astronomical research consists in the discovery of the fact, that many stars of the class styled *fixed* stars, are in reality subject to a minute movement, in virtue of which their positions in the celestial sphere are slowly shifting from year to year. This proper motion was originally found to be applicable only to a few of the principal stars, but as the observations of astronomers have acquired a greater degree of precision, the number of stars which appear to be slowly changing their position continues to increase, and the probability is, that there is no star in the celestial sphere whose position is absolutely fixed. But the results at which astronomers have arrived with respect to the parallax of the stars, combined with the relative intensities of the light of the sun and the stars, as determined by photometric experiments, tend strongly to confirm the idea that the sun is neither more nor less than a star. It is reasonable then to suppose that the sun, like the stars, should be subject to a motion of translation in space. This idea seems to have first suggested itself to Fontenelle, who refers to it in a notice on the labours of Cassini. Bradley also, at the close of his paper in which he announces the discovery of the nutation of the earth's axis, has remarked that the apparent motion of the stars may arise either from a real motion of the stars themselves, or from a motion of the solar system in space. But he was of opinion, that ages would elapse before astronomers would arrive at a definitive conclusion on this subject.

Thomas Wright, in his 'Theory of the Universe,' published in 1750, suggests, as very probable, that the sun, with his attendant planets, may be circulating round some other centre. Mayer was the first astronomer who endeavoured to deduce a trustworthy result from an examination of the proper motions of the stars. His researches were based upon a comparison of the places of eighty stars, as observed by Römer in the year 1706, with the corresponding places as determined by Lacaille and himself about the middle of the same century. The conclusion at which he arrived was, that the proper motions of the stars do not afford any evidence of a motion of the solar system in space. A remark made by Mayer on this occasion is worthy of mention. He states, that if the solar system is advancing to any particular region of the heavens, the stars in this direction will necessarily be gradually receding to a greater distance from each other, while, again, those in the opposite direction will appear to be drawn closer together. In 1783 the elder Herschel having been induced to examine the subject, arrived at a result quite different from that obtained by Mayer. His investigation was founded on the proper motions of seven of the brightest stars, as determined by Maskelyne. The result of his inquiry indicated a motion of the solar system towards a point in the heavens near the star λ Hercules, which he found to be situated in 257° of right ascension, and 25° north declination. In 1805 he subsequently resumed the subject, and obtained for the point towards which the solar system is moving, the following co-ordinates : right ascension, 245° 52′ 30″; north declination, 49° 38′.

The same subject was considered about the same time by Prévost and Klügel, whose results agreed tolerably well with those obtained by Herschel. On the other hand, Biot and Bessel, who examined the subject, arrived at the conclusion that the present state of our knowledge respecting the proper motions of the stars is insufficient to afford any trustworthy indication of the existence of a motion of the solar system in space. In recent times, however, the researches of Argelander, Lundahl, and Otto Struve, have confirmed the views of Sir William Herschel. The researches of these astronomers were based upon an examination of the proper motions of stars chiefly in the northern hemisphere. The late Mr. Galloway, however, obtained very nearly the same result by an examination of the proper motions observed in the southern hemisphere by Lacaille about the middle of the last century, and again by Johnson and Henderson in recent times. By combining his own result with the results arrived at by Argelander and Lundahl, he obtained the following values for the co-ordinates of the point in the heavens towards which the solar system is advancing :—

Right Ascension .	259° 9′·4,
Declination N. .	34° 36′·5,

these numbers referring to the equinox of 1792.

The most recent examination of this subject is due to Mr. Airy, who by a method totally different from that employed by previous inquirers has obtained a result agreeing very nearly in right ascension, but differing considerably in declination, from that hitherto arrived at.

SOLDERED JOINTS. When two pieces of metal of the same or of different natures are joined by the interposition of another metal of a more fusible character than that of the pieces to be joined, it is said that they are *soldered* together, or occasionally that they are *brazed* together. Thus, when lead has to be joined to lead, the surfaces of contact are scraped perfectly clean, and a mixed metal, composed of about $\frac{2}{5}$ of tin to $\frac{3}{5}$ of lead, is melted over the joint so as to effectually adhere to the respective surfaces. When lead has to be joined to brass, the soldering metal is usually composed of a mixture of 7 parts of tin to 5 of lead, and this alloy is also used for soldering tin pipe, or for repairing the joints of tinned iron-ware. When iron plates are joined together by soldered joints, or when copper, tin, or lead pipes are joined to iron work, the brazing or soldering metal used is composed of about 4 parts of zinc to 3 of copper, or more properly speaking, of 2 parts of fine brass to 1 of zinc, the brass consisting itself of 2 of copper to 1 of zinc. The joints themselves may be either butt joints, lapped joints, spiggot joints, crossed, or flat joints. Wrought-iron joints upon wrought-iron are made by *welding*, as also are the joints of wrought-iron upon steel, whenever it is possible to place the respective pieces in the smith's forge; the more unmanageable joints are usually brazed.

SOLDERING is the process of uniting the surfaces of metals, by the intervention of a more fusible metal, which, being melted upon each surface, serves, partly by chemical attraction, and partly by cohesive force, to bind them together. In the ordinary soldering, the alloy used as a solder must be more fusible than the metals to be united, and must have a strong affinity for them. To insure perfect union between the solder and the surfaces to which it is applied, it is essential that they be made perfectly clean and free from oxide, and that the atmosphere be excluded during the operation. This is effected in various ways, but most commonly by the use of borax, sal ammoniac, or resin, either mixed with the solder or applied to the surfaces to be joined.

The kinds of solder used for the several metals are given under SOLDERS.

Articles of *wrought-iron*, and some qualities of *steel* also, may be soldered with cast-iron; the cast-iron being repeatedly heated and quenched in water, by which it becomes sufficiently friable to be beaten to a coarse powder with an iron pestle and mortar. In making fine steel instruments, gold, either alone or with a slight alloy of copper, is often used as solder. Silver solder, being less expensive, and nearer the colour of the steel, is preferred by some for this purpose. In larger articles of iron and steel, a solder consisting of equal parts of tin and iron is sometimes used.

Common *plumbers'* solder is made of two parts lead and one part block tin; or of the same metals mixed in nearly equal quantities; bismuth is added when it is desired to make the alloy more fusible. Soft solder has two parts tin to one lead; and other alloys of tin, lead, and bismuth, are used for uniting various articles of lead, tin, pewter, and other soft compounds. Such highly fusible solders are usually cast in ingots or strips, and melted as they are used by means of an instrument called a soldering-iron, which is tipped with copper.

A curious mode of soldering is resorted to in order to fix upon the back of the dial-plate of a watch the small copper studs by which it is attached to the plate that encloses the wheel-work. The heat required for melting spelter solder would be injurious to the enamel, and therefore the studs are made of wire plated with silver, and fixed by melting the silver on their sides, and causing it to run down to their base, where a mixture of borax and water is previously laid. Thus the studs are fixed without applying the jet of the blowpipe immediately to the back of the enamelled plate.

A kind of soldering, called *burning-to*, is practised in some cases with sheet-lead, where it has been desirable to make a vessel entirely of that material; the junction being effected by pouring melted lead upon the edges to be united, until they fuse together. Somewhat similar to this is the process of *autogenous soldering*. This process, the invention of M. de Richemont, consists in the union of two pieces of metal without the interposition of any solder, by fusing them at the point of junction by jets of flame from a gas blowpipe. The apparatus used for the purpose contains a hydrogen gas generator, bellows for atmospheric air, and valves for regulating the proportion in which the gas and air are to be mixed. The joints formed in this way are neater and less liable to flaws than those made by the common process. Mr. Spencer discovered this process about the same time as M. de Richemont; and his experiments led him to suppose that, by varying the admixture of gases, a jet of flame might be produced of intensity suitable for any metal to which it may be desired to apply this mode of soldering.

The recent investigations concerning the applicability of the metal *aluminium* to purposes of use and ornament, have necessarily included the preparation of some kind of solder. It is found that aluminium cannot be soldered in the ordinary way. M. Mourey, of Paris, has devised the following plan. He puts on each surface a solder of zinc and aluminium, so as to form a thin film. Then, with a solder richer in aluminium, he joins the two pieces together. The first solder thus adheres to the metal, and the second solder to the first. The surfaces of aluminium are in the first instance prepared by a mixture of turpentine, balsam of copaiva, and lemon-juice, and strongly heated. The solder No. 1 consists of 6 aluminium and 94 zinc; No. 2 of 20 aluminium and 80 zinc.

SOLDERS. A name given to certain alloys used for uniting metallic surfaces by fusion, to effect which it is necessary that the alloy should fuse at a temperature below the melting point of the metallic surfaces to be joined. The following are some of the most important solders. [ALLOYS.]

Solder for gold	Gold (16 carats)	66·6
	Silver	16·7
	Copper	16·7
		100·0
Solder for silver	Silver	66·6
	Copper	30·0
	Brass	3·4
		100·0
Solder for brass	Copper	50
	Zinc	50
		100·0
Soft solder	Lead	67
	Tin	33
		100·0

SOLDIER is a term applied now to every man employed in the military service of a prince or state, but it was at first given to such persons only as were expressly engaged, for pay, to follow some chief in his warlike expeditions. Cæsar mentions a band of 600 men called "soldurii," who bound themselves to attend their leader in action, and to live or die with him ('De Bello Gallico,' iii. 22), but it does not appear that they served for pay. By some the word has been thought to come from "solidus," the name of a coin under the Roman empire, which may have been received as the payment for the service.

The troops which formed the armies of the Crusaders were engaged to serve for pay, for though the nobles voluntarily entered into the war, their vassals were not obliged by the tenure of their fiefs to accompany them. Père Daniel ('Hist. de la Milice Fr.,' tom. i., p. 103) expresses his belief that Philip Augustus, near the end of the 12th century, was the first of the French kings who had hired troops, at least in any considerable body, in his service; and the practice of retaining such troops appears to have been afterwards very general. It is probable that men hired for the wars were, from the time of that prince, called soudoyers or souldyours, that is, stipendiaries; but the name appears for the first time in the 'Chronicles' of Froissart, where it is applied to the hired troops both of France and Germany.

In the wardrobe account of Edward I. (1300) the term soldier occurs frequently, and Grose considers that the persons so designated were of a different class from the other troops. Some of them are called "soldiers scutifers,' or esquires; some, "soldiers constables;" and others, simply "soldiers;" but the pay of all was the same, namely, one shilling per day. ('Mil. Antiq.,' vol. i., p. 326.) From the time of Edward I. to the end of the reign of Edward III. the daily pay of a banneret was 4*s.*, and of a knight 2*s.*; that of a hobiler, a sort of light horseman, was 6*d.*; of a crossbowman, 4*d.*; and of an archer, 2*d.* In that age the stipendiary troops, or soldiers, were raised in England by commissions granted by the king to persons who undertook to enlist men for a certain pay (which was made to depend on the nature of the service), and for a certain portion of the ransom-money which might be obtained in the war.

Little change seems to have taken place in the pay of the English soldiers between the times of Edward III. and Mary. We find that during the reign of this queen the daily pay of a captain of heavy cavalry was 10*s.*, and of a cavalry soldier, 1*s.* 6*d.* The pay of a captain of light cavalry was 6*s.*, and of a soldier 1*s.* The pay of a captain of foot was 4*s.*; of a lieutenant, 2*s.*; of an ensign, 1*s.*; and of a foot soldier, 8*d.*; a halbardier and a hackbutter, on horseback, had each 1*s.* daily. In the times of Elizabeth, James I., and Charles I., the pay of the officers was a little raised, but that of a private foot-soldier was still 8*d.* per day; during the civil wars the pay of the latter was 9*d.*, but in the reign of William III. it was again reduced to 8*d.* At that time the pay of a private trooper was 2*s.* 6*d.*, and that of a private dragoon was 1*s.* 6*d.*, including in both cases the allowance for the horse. It is evident that the pay of the private soldier in later times is far from having been raised in the inverse ratio of the value of money.

While armour was in general use, the common soldiers of England were distinguished only by scarfs or by badges, on the latter of which were impressed the arms of their several leaders; but in the reign of Henry VIII. something like a uniform was worn, and it appears that the colour of the men's upper garments was then generally white; the soldiers in the king's particular service only, had on their coats a representation of the cross of St. George. However, on an army being raised in 1544, the soldiers were ordered to wear coats of blue cloth bordered with red. White cloaks marked with red crosses continued to be the uniform of the troops during the reign of Queen Mary; but in the time of Elizabeth the infantry soldiers wore a cassock and long trowsers, both of which were of Kentish gray: the cavalry were furnished with red cloaks reaching down to the knee and without sleeves. Gray coats, with breeches of the same colour, continued to be the uniform as late as the end of the reign of William III., but soon after that time red became the general colour for the coats of the British infantry soldiers.

It must be admitted that, till lately, the condition of a private soldier, both in this country and on the Continent, was unfavourable for inspiring a love of the service in his mind. Obliged to be furnished with good clothing and to preserve a becoming appearance, that which remained of his scanty pay scarcely sufficed for procuring the food necessary for his support. In his barracks he was subject to numerous petty details of duty, which produced weariness and even disgust; and, at all times, to the restraints of discipline, which deprived him of the recreations enjoyed by other classes of men; while the barracks themselves were far from being healthy or even comfortable. These disadvantages are now, however, in a great measure removed; and the pay of the soldier suffices to afford him the means of obtaining the comforts of life in a degree at least equal to those which are enjoyed by an ordinary peasant or mechanic. With the improvement of his condition, a corresponding improvement in the character of the soldier has taken place: men of steady habits are induced to enlist, and officers are enabled to select the best among those persons who present themselves as recruits for the army.

The duties of the soldier are now rendered as little burdensome as is consistent with the good of the service; the regulations promulgated by the authorities prescribe that he shall at all times be treated with mildness and humanity, and the non-commissioned officers are required to use patience and forbearance in instructing the recruits in their military exercises. When breaches of discipline on the part of the soldier oblige a commander to order the infliction of punishment, attention is paid as much as possible to render it a means of promoting a reformation of character: the lash is now very sparingly used. Wherever a regiment be now quartered, there is established for the soldiers a school, which the men are obliged, as part of their duty, to attend, and which is generally furnished with a library for their use. The library and school are formed and supported by the subscriptions of the officers, and both have been found to contribute greatly to the preservation of sobriety and good conduct among the men, by weaning them from the haunts of idleness and dissipation, and giving them a taste for useful knowledge.

In time of peace the soldier, being surrounded by the members of civil society, must, like them, conform to its laws; and, being under the influence of public opinion, he is, unconsciously to himself, held in obedience by them; so that no extraordinary coercion is necessary to keep him within the bounds of civil or military law. But in the colonies the soldier, even though he be serving in a time of peace, has many temptations to fall into a neglect or breach of discipline: he is far removed from the friends of his early life, who may have exercised upon his mind a moral influence for good: he sees around him only the conduct, too frequently licentious, of the lower orders of people in the country where he is stationed; and it may be that he is not fortified with the principles which should have been implanted in his mind by a sound education. The probability of a return to his native land before many years have passed is small, and the diseases to which he is exposed from the unhealthiness of the climate frequently terminate fatally: hence he becomes reckless from despair, and the facilities with which wine or spirituous liquors may often be obtained lead him into excesses which, while they accelerate the ruin of his health and render him unfit for duty, cause him to commit offences both against discipline and morals. Thus in the colonies there arises a necessity for greater restraints on the freedom of the soldier, and for the infliction of heavier punishments than are required at home. (Maj.-Gen. Sir Charles Napier, 'Remarks on Military Law.') Lastly, in time of war and on foreign service a vigorous discipline is essentially necessary; the privations to which soldiers are then exposed strongly induce those who are not thoroughly imbued with moral and religious principles to plunder the country-people, in order to supply their immediate wants, or to drown the sense of their sufferings in liquor.

SOLECISM (*soloecismus, σολοικισμός*), a grammatical term which is used by the later Greek and Roman writers, and by modern grammarians also, though in a somewhat different sense. It is defined by Sinnius Capito (Gell., v. 20) as an unequal and improper arrangement of the parts of speech, that is, as a violation of the rules of syntax. Quinctilian (i. s. 28, &c.) specifies four kinds of solecisms: the first consists in the addition of a superfluous word; the second, in leaving out one that is necessary; the third, in perverting the order of the words of a sentence; and the fourth, in using an improper form of a word. The ancients also used the word in a wider sense, understanding by it any kind of fault, error, or mistake, whether made in speaking, writing, or acting. Modern grammarians designate by solecism any word or expression which does not agree with the established usage of writing or speaking. But, as customs change, that which at one time is considered a solecism, may at another be regarded as correct language. A solecism therefore differs from a barbarism, inasmuch as the latter consists in the use of a word or expression which is altogether contrary to the spirit of the language, and can, properly speaking, never become established as correct language.

SOL-FA-ING. [SOLMISATION.]

SOLICITOR. [ATTORNEY; SIX CLERKS.]

SOLID, SOLIDITY. (Mechanics.) A solid body is one which is composed of matter so connected together that the relative positions of its parts cannot be altered without the application of sensible force. The force which resists the alteration of the relative positions is called force of cohesion [ATTRACTION]: the perfect absence of this force constitutes fluidity [FLUID].

SOLID ANGLE, a name given to the idea of opening conveyed by three planes which meet at a point. The properties of a solid angle are considered under the head SPHERICAL TRIANGLE.

SOLID, SURFACE, LINE, POINT. (Geometry.) We have thought it best to bring together the remarks which it is necessary to make upon these fundamental terms of geometry. According to Euclid, a point has no dimensions; a line, length only; a surface, length and breadth; a solid, length, breadth, and thickness. No one has the least doubt about each of these terms representing a clear and distinct notion already in the mind; in spite of this, however, the propriety of the definitions has been made matter of much discussion.

Space being distinctly conceived, parts of space become perfectly intelligible. Hence arises the notion of a boundary separating one part of space from the rest. That a material object, a desk or an inkstand, occupies a certain portion of space, separated by a boundary from all that is external, needs no explanation: this boundary is called surface, and possesses none of the solidity either of the desk or inkstand, or of the external space. Surface itself, when distinctly understood, is capable of division into parts, and the boundary which separates two parts of a surface has none of the surface, either on one side or the other: it therefore presents length only to the imagination. Again, length itself is capable of division into parts: the boundaries do not possess any portion of length, either on one side or the other: they are only partition marks or points. Euclid reverses the order of our explanation, requiring first the conception of a point, then of a line, then of a surface, then of a solid.

That when we think of a point, we deny length, breadth, and thickness; that when we think of a line, it is length without breadth that we figure to ourselves; that in the same manner the surface of our thoughts possesses no thickness whatever—are, to us at least, real truths. We cannot, for instance, imagine what Dr. Beddoes meant when he said ('Obs. on Demonstrative Evidence,' p. 33), "Draw your lines as narrow as you conveniently can, your diagrams will be the clearer; but you cannot, and you need not, conceive length without breadth." *Why* are diagrams the clearer, the narrower the lines of which they consist? Diagrams have no clearness in themselves; the comprehension of them is in the mind of the observer. If diagrams having (so called) lines of one-hundredth of an inch in breadth be clearer than others of five-hundredths of an inch, it is because the former approach nearer than the latter to a true representation of that which is in the mind, or of that which the mind desires to see portrayed. If the smaller the breadth the better the diagram in the clearness which it gives to the mind, it must be because the mind would have no breadth at all.

It matters nothing that the point, line, and surface are mechanical impossibilities; that no point or line, if they actually existed, could reflect light to show them; and that no surface could continue to exist for any perceptible time, even supposing it to have one moment of existence. Neither does it signify whether the ideas be necessary, or acquired from the senses; the question in geometry is, Have you got them? not, How did they come? There may be danger that some students should need at first to be frequently reminded of the abstract limits of which the conceptions must be made permanent, lest they should accustom themselves to rest in the imperfect approaches to these conceptions which are realised in their diagrams; but it is always found that a moment's recollection will produce a satisfactory answer to any question upon this point.

There is, it is true, one circumstance in which the pupil may acquire a permanently false notion of the object of geometry. If an instructor should require what is called a very well-drawn figure in every case, with very thin *lines* and very small *points*, he may perhaps succeed in giving the learner some idea that geometry consists in that approach to accuracy which constitutes practical excellence in the applications of the science. No idea can be more false: let the good line be examined under a microscope, and it is seen to be a solid mound of black lead or ink, as the case may be. Hence it is perhaps desirable that the demonstrations should be frequently conducted with what are called ill-drawn figures, in order that no reliance may be placed on the diagram, further than as serving to remind the student of the ideal conception which is the real object of his demonstration. This of course is recommended without prejudice to his learning the accurate use of the ruler and compasses for another distinct purpose, namely, the intention of producing *avowedly* approximate practical results.

It is to be noted that these definitions, so called, are in Euclid more than definitions. They appeal to conceptions supposed to exist, in words which are considered sufficient not to give, but to recall, the necessary ideas. This they actually do, to the satisfaction of the learner, who would never dream of their containing anything dubious, if it were not for the ill-advised interference of the psychologist. Whatever of pleasure or profit there may be in the subsequent union of the sciences, there is, we think, no doubt that the young geometer should not be required to examine the foundations of his notions of space: he cannot do this with effect until he has seen what these notions are by the light of their geometrical consequences.

SOLID, SUPERFICIAL, AND LINEAR DIMENSIONS. A solid, a surface, and a line, when they come to be the objects of arithmetic, are things as distinct as a weight and a time. That a surface is included by lines, or a solid by surfaces, makes no more of necessary connection between them than exists between weight and time, because the former can never be made sensible without the latter. Length only can measure length, a surface only a surface, a solid only a solid. Reasons of arithmetical convenience, not of necessity, make it advisable that whatever length may be chosen to measure length, the SQUARE on that length should be the surface by which surface is measured, and the CUBE on that length the solid by which solidity is measured. Unfortunately, if a foot be the measure of length, the square on a foot and the cube on a foot have no other names than *square foot* and *cubic foot*. The farmer with his acres, and the distiller with his gallons, have an advantage which is denied to the young mathematician. Ask the first how many acres make a gallon, and the second how many gallons make an acre, and both would laugh at the question; the third is allowed an indistinct conception of measuring surfaces and solids in feet or inches, as if they were lines, from the occurrence of the same word in all his measures.

Length is said to be a quantity of one dimension, surface of two, and solidity of three. The right line, the right surface or RECTANGLE, and the right solid or rectangular PARALLELOPIPED (the figure of a box, a die, a plank, a beam, &c.), are the implements of mensuration. Every surface must be reduced to the second form, and every solid to the third, before it can be measured. The rules (which tacitly contain these reductions) for measuring different superficial or solid figures will be found under the several heads: the two fundamental theorems by which measurement becomes practicable are as follows:—

1. The numbers of linear units in the two sides of a rectangle being multiplied together, give the number of superficial units, square units, or squares on the linear unit, which the rectangle contains. Thus a rectangle of 2½ by 4⅓ feet contains $\frac{5}{2} \times \frac{13}{3}$, or $\frac{65}{6}$, or 10⅚ *square* feet.

2. The numbers of linear units in the length, breadth, and thickness of a right solid, being multiplied together, give the number of solid units, cubic units, or cubes on the linear unit, which the right solid contains. Thus a plank of 2¼ inches broad, 1½ inch thick, and 10⅓ inches long, contains $\frac{9}{4} \times \frac{3}{2} \times \frac{31}{3}$, or $\frac{279}{8}$, or 34⅞ *cubic* inches.

SOLIDIFICATION. If heat be abstracted in sufficient quantity from a body in the liquid state, it will become solid. This change in the case of water is termed *congelation*. During solidification, the heat of liquefaction becomes apparent, as explained under LATENT HEAT. Certain liquids, however, have not been solidified at so low a temperature as −166° Fahr., such as alcohol, ether, and some others, noticed under GASES, LIQUEFACTION OF, where will be found a list of those gases which have been solidified under cold and pressure.

SOLIDITY. For the signification of this word in its strictest sense the reader is referred to IMPENETRABILITY; but, as the word is frequently employed to designate a condition of material substance in contradistinction from liquidity, or a gaseous form, it may in this sense be defined to be a state of a body in which the force of cohesion between the molecules is such that these require a certain amount of force to separate them from one another; and, at the same time, they are subject to small variations only of their mutual distances by the application of any quantity of heat less than that which would reduce them to ashes or convert them into fluids. The expansion of solids by heat is noticed under HEAT; see also SPECIFIC HEAT.

SOLIDS, REGULAR. [REGULAR FIGURES.]

SOLITARIUS (the Hermit), an obscure constellation of Lemonnier, which, having been admitted into the Astronomical Society's lists, appears here. It is situated a little above Centaurus, near the tail of Hydra. There are no conspicuous stars in this constellation.

SOLMISATION, or *Sol-fa-ing*, in singing, is the art of applying to the seven notes of the scale certain syllables, having no meaning in themselves, but containing the first five vowels, according to the French method, and the first four according to the system adopted by the Italians and English.

This art was practised by the Greeks; but the six syllables now in use are generally attributed to Guido d'Arezzo. These he selected, on account of their furnishing all the vowel sounds, from the following stanza of a monkish hymn to St. John the Baptist:—

> "*Ut* queant laxis,
> *Re*sonare fibris
> *Mi*ra gestorum
> *Fa*muli tuorum
> *Sol*ve polluti
> *La*bii reatum.
> SANCTE JOANNES."

In what is called the hexachord system [HEXACHORD], these syllables were found sufficient. When, however, that absurd method began to be disused, the addition of a name for the seventh of the scale became necessary, and Le Maire, a French musician of the 17th century, has the credit of having introduced for this purpose the syllable *si*. The Italians rejected the French *ut*, and substituted the more euphonous syllable *do*, which is also adopted in England. The syllables therefore now used by the Italians and English are as follows:—

Do,	Re,	Mi,	Fa,	Sol,	La,	Si,	Do.
C,	D,	E,	F,	G,	A,	B,	C.

To these syllables the English give the Italian pronunciation.

SOLOMON, THE SONG OF, or THE BOOK OF CANTICLES (שִׁיר חַשִּׁירִים; *Ἆσμα τῶν ᾀσμάτων*, 'Canticum Canticorum,' our 'Song of Songs') a canonical book of the Old Testament.

The canonical authority of this book has been much disputed. It is now admitted that it formed part of the Jewish canon. It is found in the oldest Christian catalogues of the sacred books, and in all the ancient versions, though it is not quoted in the New Testament. The objections to its canonical authority are now therefore derived solely from its internal character, and may be summed up in the following argument: that the book cannot form a part of Holy Scripture, since it contains no religious truth, unless we interpret it after a fashion for which there is no authority.

The book is a poem, or collection of poems, describing in imagery which is certainly warm, but to an oriental taste perfectly delicate, the chaste loves of a bridegroom and his bride. It bears the name of Solomon in its title, 'The Song of Songs, which is Solomon's;' and is supposed to be the only remaining one of the thousand and five songs which we are told that that monarch composed. According to the common opinion it was composed as an epithalamium at the marriage of Pharaoh's daughter with Solomon, who are respectively the bride and bridegroom of the poem; but under the guidance of divine inspiration it was so constructed as to form a mystical allegory representing the relation between Christ and his church.

First, then, with respect to its date and author. An attempt has been made, supported by Kennicott, Eichhorn, Jahn, and Rosenmüller, to prove the poem later than the Babylonish captivity, but Ewald, an excellent judge, and De Wette, agree in referring it to the time of Solomon. The style and language are not more different from that of the 'Book of Proverbs' than might be expected from the difference of the subjects. But the structure and contents of the poem are alleged as presenting insuperable obstacles to the supposition that Solomon was the author. Again, with reference to the bride, it is contended that the poem itself proves her to have been not an Egyptian princess, but an Israelite. This point is very strongly brought out by Dr. Mason Good. On all these points the difficulty is much increased by the highly coloured imagery of the poem. But the first difficulty may perhaps be explained by supposing one or more changes of scene: there seem in fact to be several. The question respecting the person designed to be represented by the bride, it has been attempted to solve in various ways. Dr. Mason Good imagines that the poem describes a *love-match* which Solomon made with some Israelitish woman after his *political* marriage with Pharaoh's daughter. A third mode of explanation, which if adopted would cut the knot, is that of Dr. James Bennett, who supposes that the poem never had any literal reference at all to an actual marriage, but is purely an allegory descriptive of the mutual love of Christ and his church. But the minute allusions, especially those to Solomon, which are contained in this poem, are a most formidable objection to such an explanation; and even those critics who contend most strongly for the purely allegorical character of the 45th Psalm, maintain as strongly that the Song of Solomon has a literal as well as a spiritual meaning. (See especially Bishop Horsley's 5th 'Sermon.') The distinction however between the two questions of who was the author and who were the parties described, ought not to be lost sight of, as it too often has been. Finding the book in the Jewish canon, the presumption is that it is a genuine part of Holy Scripture, and is intended to teach religious truth. This presumption is strengthened, if it can be proved that Solomon was the author, since we have at least one other book of his in the sacred canon; but it is not disproved even if the poem should be found to have nothing to do with Solomon either as its author or its subject.

It is admitted that from a very early period the oriental nations have been accustomed to express religious sentiments allegorically under the guise of amatory poems, of which the Gitagovinda is an example. To this day the Egyptian Arabs, at their religious festivals, sing songs resembling this, in which the prophet is the beloved object, and which are only intended to have a spiritual sense. (Lane's 'Modern Egyptians,' vol. ii.) Mr. Lane in fact gives passages from these songs strikingly parallel to passages in Solomon's Song. Neither is it denied that similar imagery is used with a similar meaning in other parts of the Bible (Psalms, xlv.; Isaiah, liv.; lxii. 4, 5; Rom., vii. 4; 2 Cor., xi. 2; Ephes., v. 23–32; Rev., xix. 7; xxi. 2–9), and also the opposite figure of representing idolatry and apostacy under the image of adultery or whoredom. But it is said that in all such passages the allusions are more distant, and enter less into detail than is the case in Solomon's Song, and that in them the religious sense is made so prominent that one can scarcely fail to perceive it. The first part of this assertion does not appear to be sustained by fact. Any one who examines the passages carefully, especially those which relate to spiritual adultery, will find allusions inferior in delicacy to the grossest which can be produced from Solomon's Song. The latter condition does not appear to be necessary (as has been argued above) to establish the allegorical meaning of such imagery, when occurring in a canonical book: neither is the spiritual sense always so obvious. For example, there is nothing in the 45th Psalm, except one or two expressions which could not by the greatest hyperbole refer to a human being, to lead us to suspect its spiritual meaning. The fact that the 45th Psalm is quoted in the New Testament, and that the Song of Solomon is not so quoted, is no objection to this view of the subject, for the quotation of the one sanctions the general principle of interpretation, while the silence respecting the other proves nothing, knowing as we do that the New Testament writers adopted the Old Testament canon as it existed in their day, and that this Song was in that canon. Nearly all expositors, both Jewish and Christian, have adopted the allegorical interpretation, though they have explained the allegory in different ways. The Chaldee Targum considers it as a figurative description of the love of God to Israel, as shown in delivering them from the Egyptian slavery, supporting and comforting them in the wilderness, and bringing them into the promised land. Christian expositors, from Origen downwards, have generally understood it as descriptive of the union between Christ and the church; but some few have explained it in a different way. Those who acknowledge its canonicity, but reject the idea of a reference either literally to Solomon or figuratively to Christ, take its admission into the canon to be a divine recommendation and praise of a single virtuous marriage as opposed to polygamy and concubinage. This was latterly the opinion of the most distinguished modern opponent of its canonicity in England, Dr. J. Pye Smith. Various opinions are held as to the structure of the Song, the best of which appears to be that which takes it to be a pastoral-nuptial song in a dramatic form.

(The *Introductions* of Eichhorn, Augusti, Jahn, and Horne; *Papers* by Dr. Smith, Dr. Bennett, and others, in the 'Congregational Magazine' for 1837 and 1838; *The Song of Songs*, by Mason Good, Lond., 1803; other *Commentaries* in Horne, vol. ii., part ii.; Lowth's *Prælections;* Hirzel, *Das Lied der Lieder, oder Sieg der Treue*, Zurich, 1840; Fava, *La Cantica delle Cantiche*, Milano, 1840.)

SOLOMON, THE WISDOM OF (*Σοφία Σαλώμων*), an apocryphal book of the Old Testament, ascribed to Solomon, but manifestly written long after his time. It is not known to have ever existed in Hebrew, and it contains Greek ideas and expressions which prove it to belong, if to a Jew at all, to one of the Alexandrian school. There are in it historical references utterly at variance with the state of things in Solomon's reign, and quotations from Isaiah and Jeremiah. Internal evidence would point to the end of the second or beginning of the 1st century B.C. as the time of its composition. It is commonly ascribed to Philo the Jew, but the style is quite different from his genuine writings. It was badly translated into Latin before the time of Jerome, who did not revise the version. The fathers of the church considered it apocryphal; but it was pronounced canonical by the third council of Carthage (A.D. 397), and again by the council of Trent.

It consists of two parts. The first part (chap. i.–ix.) contains the praise of wisdom, an exhortation to all, and especially to kings, to seek it, and the manner in which it is to be obtained. The second part (chap. x.–xix.) brings forward examples from history of the happiness that springs from wisdom and the misery entailed by folly. Throughout the book Solomon is represented as speaking; and the work is evidently an imitation of his proverbs. It is remarkable as being the earliest Jewish work extant which contains a clear statement of the doctrine of rewards and punishments in a future state.

SOLSTICES, the points of the ecliptic which are highest above the equator, at which, the sun's motion in declination being imperceptible, the days remain sensibly unaltered in length for several days together, as they would do if the sun absolutely stood still: whence the name. [SUN.]

SOLUBILITY. [SOLUTION.]

SOLUTION. When the force of ADHESION is exerted between a solid and a liquid with sufficient energy to overcome the cohesion of the former, the substance is said to be soluble, or to undergo solution, or to be dissolved. The solution of sugar in water, of resin in spirits of wine, of silver in mercury, is now regarded as a form of adhesion. Certain liquids are also soluble in other liquids, gases in other gases, and gases in liquids, as noticed under DIFFUSION. For the solubility of gases in liquids, we refer to GAS. In the present article we may give a few details respecting the solution of solids in liquids.

The liquid which effects the solution is usually termed the *solvent*, but sometimes the *menstruum*. Particular solutions have also special names, such as *syrup*, which is applied to the solution of sugar in water, while *tincture* refers to a solution of a solid in alcohol. When a liquid can no longer dissolve further portions of the solid, it is said to be *saturated;* that is, the force of cohesion balances that of adhesion. Generally, however, an elevation of temperature, by diminishing cohesion, will increase the solvent powers of the liquid. But there are cases in which cold appears to favour solution: thus lime and some of its salts dissolve more readily in water just above the freezing-point than when boiling. Crystallised sulphate of soda requires about ten times its weight of ice-cold water for solution, and its solubility increases rapidly with the temperature up to 91° Fahr., from which point up to the boiling-point of the solution the solubility decreases; and the liquid, saturated at 91°, deposits a portion of the salt by increasing the temperature. Seleniate of soda and sulphate of iron afford similar results, which are due probably to the fact that heat diminishes adhesion as well as cohesion, but the former force decreases more rapidly than the latter. If a liquid added to a solution have a stronger adhesion to the solvent than to the substance dissolved, the latter will often be thrown down in a pulverulent state: thus, the addition of water to camphorated spirit will throw down camphor.

Solution is favoured by increasing the extent of surface in the solid, as by reducing it to powder. In general, the first portions of a solid disappear rapidly, and the after portions more and more slowly until saturation is reached. Solids present innumerable degrees of solubility; for while some bodies, such as sulphate of baryta, are almost insoluble, and sulphate of lime only soluble in about the proportion of 1 part in 700 parts of water, 1 part of sulphate of potash will dissolve in 16 parts of water, and 2 parts of sulphate of magnesia will dissolve in only 3 of water. It is remarkable that water saturated with one salt will dissolve others. As aqueous solutions of solids are heavier than water, the degree of solubility of a solid may be judged of by suspending it in a glass of water, and watching the current as it descends. "If it fall rapidly, and in dense striæ, it will indicate rapid solubility, and the formation of a dense solution; if it fall in a very narrow stream, it will indicate only moderate or slight solubility; and by its descending rapidly or in a slow broad stream, or by resting about the substance, a judgment may be made of the comparative density of the solution produced. If no descending current appear, nor any fluid round the substance of a refractive power or colour different to that of the water, then the body must be very nearly, if not quite, insoluble at common temperatures." (Faraday, 'Chemical Manipulation.') The taste will also frequently give an indication of the solubility of a solid.

In general, a solution due to adhesion partakes of the properties both of the solvent and of the substance dissolved. Where chemical change intervenes, we have the properties of a third body. Hence, in cases of simple solution, the solvent and the body dissolved have, to some extent, properties in common, as when mercury dissolves many of the metals, and oils dissolve fatty bodies and each other; but in cases of chemical action, the affinities are strongest between bodies the most dissimilar, as when the acids dissolve metals or their oxides, oils the alkalies, and so on.

The uses of solution are numerous. It allows a body to be purified by filtration or crystallisation, so that one substance may be separated from another, either by crystallisation or by the use of such fluids in succession as have a solvent power over one or more of the substances present. By means of solution, substances are prepared for the exertion of chemical action, and all obstructions due to the attraction of aggregation removed.

SOLUTION. (Mathematics.) By the solution of a problem should be meant the method of finding that which the problem requires to be found: but the word is frequently understood to apply to the answer itself.

A solution is given when the problem is reduced to any other which was supposed to be known before the first was presented: the difficulty peculiar to the given problem is removed as soon as it is shown to be capable of reference to another and a lower class. Thus, though properly speaking a problem is not solved until the answer is presented in numbers, yet it is not thought necessary to require that such a result should be attained, provided the steps which are left are such as are well known and generally admitted. Thus an equation would be said to be solved were it found that the roots required are those of a given quadratic; for no one is supposed ignorant of the mode of then finding them.

A *geometrical* solution, in the strict sense of the word, is one in which only the means of construction admitted by Euclid, or others deducible from them, are employed in its attainment. This is the least finished of all solutions; for a mode of laying down the various points which terminate lines is not, generally speaking, a mode of ascertaining the ratio of these lines. Nor must it be forgotten by the admirers of geometry that the most important part of a result, the expression of the ratios which the answer bears to the several data, is only indirectly obtained in their favourite method.

When more means than those allowed by Euclid are employed, the solution used to be called *mechanical*. It is rarely that such a solution is now employed.

An algebraical solution is one which employs algebra and arithmetic, to the exclusion of geometrical construction; that is, one in which the answer can always be directly calculated from a formula. Geometrical construction may be necessary for the demonstration of the solution: it is enough that the answer contain no directions to find lines or surfaces by construction.

An approximate solution is one which has an amount of inaccuracy necessarily. Thus if $3 + \sqrt{2}$ were the root of an equation, this solution would not be called approximate; for though $\sqrt{2}$ cannot be perfectly represented in a finite form, the symbol itself contains the mode of attaining the result with any degree of exactness short of perfection. But if $\sqrt{2}$ were found to five decimal places, the answer 1·41421 would be called an approximate answer. Most solutions must terminate in an approximate representation. [TRANSCENDENTAL.]

SOLVENT. [SOLUTION.]

SOMNAMBULISM, a word of modern origin, which means strictly and etymologically *sleep-walking;* it is however generally used in a more extended signification to comprehend all the phenomena that take place when a person, apparently insensible to external objects, acts as if he were in a state of consciousness: and this is the sense which the word will bear in this article. M. Bertrand, in his 'Traite du Somnambulisme' (8vo., Paris, 1823), divides those phenomena into four classes: 1, essential (or *proper*) somnambulism, which arises from some particular disposition of the nervous system in persons who in other respects apparently enjoy perfect health; 2, symptomatic (or *morbid*) somnambulism, which occurs in the course of certain diseases; 3, artificial somnambulism, which is occasioned by the proceedings employed in animal magnetism or mesmerism; and, 4, ecstatic somnambulism, which is the result of a sort of religious enthusiasm. The same division of the subject will be here adopted.

I. *Essential* (or *Proper*) *Somnambulism* is intimately connected with the subject of sleep and dreaming; and in fact "a somnambulator," as Dr. Pritchard says, "is nothing but a dreamer who is able to act his dreams." [DREAMS.] [SLEEP, in NAT. HIST. DIV.] As a minute inquiry into the physiology of these two phenomena would here be out of place, the reader must consult the articles already given on these subjects. This form of somnambulism was noticed by the ancients. The author of the treatise 'De Morbo Sacro,' that commonly goes under the name of Hippocrates, says that "he knew many persons who used to groan and cry out in their sleep, and others that seemed to pant for breath (*πνιγομένους*), and others that would get up and run out of the house and act like madmen till they were awakened, after which they were in good health and sound sense as before, only rather pale and weak" (tom. i., p. 588, ed. Kühn). Aristotle tells us that "there are individuals who rise in their sleep and walk about, seeing as clearly as those that are awake." Diogenes Laertius mentions ('De Vitis Philosophorum, Pyrrho,' lib. ix.) that a Stoic philosopher named Theon was a sleep-walker; and Galen says ('De Motu Musculorum,' lib. ii., cap. 4, tom. iv., p. 435, 436, ed. Kühn) that he would not believe that people ever fell asleep while walking, until one night when walking along the road he did so himself, and went on for about a furlong, sleeping and dreaming, till at last he was awakened by kicking against a stone. "And this," adds he, "is the reason why people cannot go on walking for any distance in their sleep, because they cannot meet with a perfectly smooth road;" in which he is not quite correct, as we often find that both the bodily and intellectual powers of the individual are more active and developed in his sleep then when he is awake, and that he is then able to perform feats which at any other time he would shudder at. The instances on record of this species of somnambulism are so numerous that it is difficult to select the most interesting; one or two examples however must be given, and for a more copious collection the reader must be referred to some of the works whose titles will be given in the following part of this article.

Several interesting cases of somnambulism will be found in Muratori's work, 'Della Forza della Fantasia Humana;' some of them given on the authority of Gassendi. One of Gassendi's somnambulists used to rise and dress himself in his sleep, go down to the cellar and draw wine from a cask. He appeared to see in the dark as well as in a clear day; but when he awoke, either in the street or cellar, he was obliged to grope and feel his way back to his bed. He always answered his wife as if awake, but in the morning recollected nothing of what had passed. Another sleep walker, a countryman of Gassendi's, passed on stilts over a swollen torrent in the night, but on awaking was afraid to return before daylight, or until the water had subsided. This species of somnambulism has been known to be hereditary. Horstius, in his work 'De Natura, Differentiis, et Causis eorum qui Dormientes ambulant' (seu 'de Noctambulonibus'), Lips., 1595, 8vo., p. 172, mentions three brothers who were affected with it at the same time; and Willis knew a whole family that was subject to it. Perhaps however these may rather be considered as instances of the influence of example and of the power of unconscious imitation, which sometimes renders it in a manner contagious. Of this there is a curious example given by Dr. Pezzi, in a work entitled 'Scretti di Medico Argomento,' Venez., 1813. It appears that his nephew, after reading more than once the history of a somnambulist, was himself seized with this affection; and also that the servant who attended him soon began to exhibit in his own person similar phenomena.

Essential somnambulism occurs in many persons (says Dr. Good) without any manifest predisponent cause, though it is generally connected with a considerable irritability of habit. A morbid state of the stomach, where this habit exists, has very frequently proved an exciting cause; and where this is the case, the attention of the physician must of course be directed to that quarter. With respect to the mode of treatment during the fit, though it has sometimes been recommended to employ violent means, so as to awaken the somnambulist suddenly, and to repeat this as often as the attacks come on, until they have completely ceased; yet M. Bertrand warns us against such a proceeding. "If, in the first place," says he, "sensibility is completely extinguished, all the means employed to awaken the somnambulist will be useless; secondly, even when it is possible to awaken him at once, the sudden shock produces serious consequences; thirdly, as somnambulism is often the result of a salutary crisis of nature, one is never sure of not hurting the patient by suppressing it; and, lastly, the sudden suspension of habit of the animal economy that has been contracted for a long time, must in all cases be attended with danger." He adds that the best plan is to try to put oneself in connection with the patient by entering into the course of ideas by which he is occupied during the attack, and so endeavour to direct him in a reasonable manner.

II. *Symptomatic or Morbid Somnambulism* generally presents itself as one of the phenomena attending catalepsy. [CATALEPSY.] This form of somnambulism does not appear to have been noticed by the ancients; but there are many cases on record long before the time of Mesmer, as well as others described by persons unacquainted with and even opposed to the doctrines of animal magnetism. The following case is given by Colquhoun, on the authority of Sauvages, and may be found in greater detail in the 'Hist. de l'Académie des Sciences,' for the year 1742: A girl of twenty years of age was frequently attacked with cataleptic insensibility, during which she continued stiff and deprived of all sensation, whether standing, sitting, or lying, in the position she might happen to be in at the time of the commencement of the attack, and she could be pushed forward, like a statue, when it was wished to remove her from one place to another. She was afterwards placed in a different state, which commenced with the same deprivation of sense and motion, but at intervals presented a wonderful kind of animation. She first became motionless, then, some minutes afterwards, she began to yawn, sat up on the bed, and enacted the following scene, which she repeated at least fifty times. She spoke with an unusual liveliness and cheerfulness, and what she said was a continuation of what she had spoken in her previous fit, or a repetition of some part of the catechism which she had heard read on the preceding evening. She frequently addressed her acquaintances in the house, and sometimes made ironical applications of moral apophthegms to them under feigned names with open eyes, and such gestures as she had made the previous evening. That during all this time she was not awake, was clear from various experiments. A hand was suddenly passed near her eyes, without producing any motion in the eyelids or any attempt to evade it, or interrupting her speech in the slightest degree. The same thing happened when a finger was suddenly approached close to her eye, or a burning taper held so near to it that the hair of her eyelids was actually burnt, and also when any one called loudly into her ear from behind, or threw a stone against the bedstead. Nay more, brandy and spirit of hartshorn were poured into her eyes and mouth; Spanish snuff was blown into her nostrils; she was pricked with needles; her fingers were wrenched; the ball of her eye was touched with a feather, and even with the finger: yet she manifested not the slightest sensation. During these trances she always began to speak with more than usual animation; soon afterwards, she sang and laughed aloud, attempted to get out of bed, and at length sprang out of it and uttered a cry of joy. She kept the middle way between the bedsteads as well as when awake, and never came against them—turned dexterously round between the bedsteads and a concealed closet, without ever groping her way or touching the objects; and after turning round, she returned to her bed, covered herself with the clothes, and again became stiff as at the commencement. She then awoke as if from a profound sleep, and when she perceived, from the appearance of the bystanders, that she must have had her fits again, she wept the whole day for shame, and never knew what had happened to her during the paroxysm. The above is by no means one of the most wonderful cases of somnambulism occuring during a cataleptic seizure, but it has been chosen on account of the respectable authority on which it rests. Those recorded by M. Petetin ('Mémoire sur la Découverte des Phénomènes que présentent la Catalepsie et le Somnambulisme, &c.,' 1787; and 'Electricité Animale prouvée par la Découverte des Phénomènes Physiques et Moraux de la Catalepsie Hystérique, et de ses Variétés,' Lyon, 1808), are not perhaps less authentic.

III. *Artificial Somnambulism*, or that which is occasioned by the proceedings employed in animal magnetism, is not expressly mentioned by any ancient writer, but some lines by Solon, and a verse in Plautus ('Amphitr.' i. 1–157) have been supposed by some persons to allude to these manipulations. As an account of the doctrines of Mesmer has been already given under the head of ANIMAL MAGNETISM, it will be sufficient here to refer to the 'Rapport sur les Expériences Magnétiques faites par la Commission de l'Académie Royale de Médecine [à Paris], lu dans les Séances des 21 et 28 Juin, 1831, par M. Husson, Rapporteur.'

With respect to the phenomenon of somnambulism as caused by mesmerism, or animal magnetism, so much credulity and deception have been brought to light in connection with it, that a person cannot be too cautious in sifting and weighing the evidence on which each of the alleged instances rests; but after all this mass of knavery and folly has been cleared away, there still remain a large number of instances which cannot be disbelieved without discarding all historical evidence whatever. For more information on the subject the reader may consult, besides the works already quoted, the Rev. Chauncey Townshend's work on Somnambulism, and 'Le Magnétisme Animal en France,' by M. Bertrand, Paris, 1826.

IV. *Ecstatic Somnambulism.*—M. Bertrand has given this name to that species which is produced by a high exaltation of the mind, and becomes in a manner infectious by sympathy in such persons as are predisposed and subjected to the same influences. Of this last species, the *devotional ecstasis* is perhaps the most frequent and the most remarkable; and this has been supposed to have had some connection with the oracles and other miraculous stories of antiquity. M. Bertrand has, however, for obvious reasons, selected his instances from four different periods in modern times, in each of which the devotional ecstasis appeared as a sort of epidemic, and presented symptoms very similar to those occurring in the three former species of somnambulism. The first series of phenomena are those which took place in connection with the burning of the unhappy Grandier on the charge of sorcery at Loudun, in 1634, an account of which may be found in Bayle ('Dict. Hist.,' art. 'Grandier'); or in the 'Hist. des Diables de Loudun,' by a Protestant Refugee, Amst., 1693, 12mo. The next instances are extracted from a scarce work entitled 'Théâtre Sacré des Cévennes,' and relate to the French Protestants who, after the revocation of the Edict of Nantes, 1685, went by the name of the 'Trembleurs des Cévennes,' and were persecuted and massacred in those mountains. The third epidemic broke out at the tomb of the Abbé Pâris in the church of St. Médard, at Paris, about the year 1731. These are perhaps the most celebrated of all, as having been selected by Hume to oppose to the miracles of the New Testament. The original and authentic account of them was published by M. Carré de Montgeron, in a work entitled 'La Vérité des Miracles opérés à l'Intercession de M. de Pâris,' &c., 2 vols. 4to, 1737, 1741; and they are examined at some length and with great acuteness by Bishop Douglas, in his 'Criterion, or Miracles Examined,' &c. To these he has added, fourthly, some considerations on the state produced in the patients who, towards the end of the last century, were exorcised by a priest named Gassner, at Ratisbon. An account of these (supposed) miraculous cures is to be found in a work entitled 'L'Antimagnétisme; ou Origine, Progrès, Décadence, Renouvellement, et Réfutation du Magnétisme Animal,' 8vo, Londres, 1784 (pronounced by M. Deleuze to be the ablest publication that had appeared against the doctrines of Mesmer), which account is extracted from a work called 'Procès-verbal des Opérations Merveilleuses, &c., par le Ministère du Sieur Gassner,' &c., Schillingsfürst, 1775. As, however, neither these nor many other examples that might be brought forward can be fully noticed here, it has been thought sufficient to point out the places where further information may be procured.

SONG, a term applied to either a short poetical or musical composition, but most frequently to the two in union.

As denoting a musical composition, *song* is used, in this country, to signify a vocal melody of any length or character, and not confined to a single movement; and while the solemn air of the oratorio, and the *aria grande* of the Italian opera, are frequently, though erroneously, called by this name, the same is bestowed on the short, simple ballad. But this is only one instance among many of the defective state of our musical nomenclature. Of the varieties of *song*, see AIR, BALLAD, CANZONET. The term however is not absolutely unlimited in its meaning, for, as regards performance, it is most frequently confined to an air for a single voice. Thus our composers, especially in the 16th and 17th centuries, often entitle their productions for more than one voice, 'Part-Songs.'

Concerning the *songs*, or *Σκόλια*, of the Greeks, see Music and Scolia. Of the Roman song, musically considered, we are without information. Having more of war than of taste in their nature, the Romans bestowed little thought on music, and coldly adopted what was transmitted by the elegant Greeks. But music, as the term is at present understood, is an art exclusively modern, and cannot be said to have existed till the invention, or at least the use, of counterpoint.

The poetry of modern songs has, in too many instances, degenerated, while the music of them has gradually improved. England, from about the middle of the last century till a recent period, furnished its full share of beautiful songs (this term excluding all airs of greater pretensions) to the general stock. France rather later began to contribute its fair quota; and however opinions may differ respecting the merit of earlier French melodies, it seems to be agreed that they may now compete with those of most other nations. But it must be admitted that Germany of late years has taken the lead in this, as in higher departments of music.

SONG OF SOLOMON. [Solomon's Song.]

SONNET (Italian, *Sonata*, *Sonetto*), a form of poetry much used by the Italian and Spanish poets, but which our deficiency of rhymes has caused to be more sparingly used in English. The sonnet properly consists of two quatrains, having properly but two rhymes, and two tercets. The last six lines are susceptible of various arrangements; the one usually adopted in English is the rhyming of the fifth and sixth lines together, frequently after a full pause, so that the sonnet ends with a point, as in an epigram. The Italians consider the best form to be the rhyming together of the three uneven and the three even lines; but our poverty of rhymes causes us to prefer the rhyming of the first and fourth, second and fifth, third and sixth lines: this, with a break in the sense at the third line, constitutes also a legitimate sonnet, of which the Italians have given abundant precedents. We need scarcely observe that all our poets have held themselves at liberty to vary the form of the sonnet. The lightness and richness of the Italian and Spanish languages enable their poets to express every feeling or fancy in the sonnet; but with us it has been found most suitable to grave, dignified, and contemplative subjects. Hence Milton and Wordsworth are our best writers of sonnets.

SONOROUS VIBRATIONS. When the air or other elastic body is made to vibrate with sufficient rapidity, *sound* is produced. [Acoustics.] During such vibrations the molecular arrangement of the sounding body becomes changed, but returns to its normal state when the vibrations cease. [Nodal Points and Lines.] It is stated (Bird's 'Natural Philosophy,') that if a copper ribbon 9 feet long, ·4 inch wide, and ·04 inch thick, be vibrated, its length will appear to be unaffected. If it be stretched by a weight of 90 lbs., its length will remain the same until it be made to vibrate, when it will become permanently lengthened by 6 or 7 inches. When sonorous vibrations are isochronous a perfect *sound* or *tone* is produced; when irregular, a *noise*. For the phenomena produced by the reflection of sonorous vibrations, see Echo, and for their interference Acoustics and Interference. For the production of sonorous vibrations during the cooling of heated metals, see Thermophone. For the different kinds of vibrations, see Vibrations.

SOOT is that portion of fuel which escapes combustion, and which is mechanically carried up and deposited partly in chimneys and partly in the air. The soot of coal and that of wood differ very materially in their composition; the former indeed does not appear to have been accurately analysed, but it evidently contains more carbonaceous matter than the latter. Coal-soot contains substances usually derived from the distillation of organic matters; it contains sulphate and hydrochlorate of ammonia, and has been used for the preparation of the carbonate; to hot water it yields a brown bitter extract, and it contains an empyreumatic oil; but its great basis is charcoal in a state in which it is capable of absorbing ammonia from the air, and hence with the ammoniacal salts it already contains, it is used as a manure, and acts very powerfully as such. Sir H. Davy observes that for this purpose it is well fitted to be used in the dry state, thrown into the ground with the seed, and requires no preparation.

The soot of wood has been minutely analysed by Braconnot, who found it to consist of the following substances:—

Ulmin (about)	30·20
Azotised matter	20·00
Carbonate of lime and traces of carbonate of magnesia	14·66
Water	12·50
Acetate of lime	5·65
Sulphate of lime	5·00
Acetate of potash	4·10
Carbonaceous matter insoluble in alkalies	3·85
Ferruginous phosphate of lime	1·50
Silica	0·95
Acetate of magnesia	0·53
Asbolin (a peculiar acrid and bitter principle) about	0·50
Chloride of potassium	0·36
Acetate of ammonia (about)	0·20
Acetate of iron (a trace)	..
	100·

Braconnot considers the ulmin as absolutely similar to that obtained artificially by the action of potash on wood-sawdust, but Berzelius is of a different opinion, and calls it *gein*. The azotised matter is very soluble in water, and insoluble in alcohol. As coal-soot contains much more carbonaceous matter than wood-soot, and also a much larger portion of ammoniacal salts, it must be more active as a manure, and altogether a more useful substance.

SOPHISM (*Σόφισμα*), that superficial and incomplete aspect of the truth, which at first sight looks like the truth, but on closer inspection turns out to contain some radical error. This seems the most correct definition, but the word is used loosely. Its general signification, namely, a *specious* proposition, is perhaps nearest the mark. Truly considered, most errors are sophisms, for errors are not direct contradictions to the truth, but simply the leaving out of view one or more elements of the truth, and seizing on only one or two elements, and declaring them to constitute the whole truth. Victor Cousin defines error to be "One element of thought considered exclusively, and taken for the complete thought itself. Error is nothing but an incomplete truth converted into an absolute truth." ('Introduction à l'Hist. de Philosophie,' Leçon 7.) Spinoza had before defined "falsity to be that privation of truth which arises from inadequate ideas." ('Ethica,' b. ii. prop. xxxv.) It is sometimes a mere confusion of terms; as in the common example of—Bread being better than paradise; because bread is better than nothing, and nothing is better than paradise—the confusion arises from both the "nothings" being used substantively; whereas it is only the first that is so used; the second is affirmative, and expresses "there is nothing better." A sophism is therefore the use of some word in a different sense in the premises from that in the conclusion, and this is the definition of Aristotle ('Top.' viii. 11): "When the discourse is a demonstration of anything, if it contain anything which has no relation to the conclusion, there will be no syllogism; and if there appear to be one, it will be a sophism, and not a demonstration."

This confusion of words and ideas is the origin of all errors and sophisms; but though errors and sophisms are logically constituted alike, yet the instinctive sense of mankind marks the difference between incomplete views (error) and wilful perversion (sophism). In all cases a sophism is supposed to be recognised as such by the sophist. It is an endeavour on his part to "make the worse appear the better reason." It is the consciousness then of the sophist which distinguishes and renders odious his error as a sophism.

SOPHISTS. The race of sophists took its rise in Athens about the 5th century B.C., when Athens was a real democracy. From the necessity every man was under of pleading his own cause before the dicastery, in any case before the court, whether as plaintiff or defendant; from the political power which every citizen possessed, but could scarcely exercise with effect unless able to speak fluently; the teaching of rhetoric, or the arts of speaking and arguing logically, came to be in much request. The age was also a sceptical, and therefore an investigating one. But though flourishing in Athens, sophists and their teachings were not confined to that city, but extended throughout all the Grecian republics, and occasionally to the courts of tyrants. They went about Greece discoursing and debating, and sometimes educating the youth of rich and noble families. They were not, strictly speaking, a sect; indeed the name signifying only a wise or clever man, had been so applied from the earliest times of Greece; and Socrates, Plato, and other eminent men were all called sophists.

The disrepute attached to the name arose apparently from the facts of the teachers accepting payment for their lessons, and thence proceeding to inculcate not the desire for truth, but the means of securing victory by the use of specious fallacies. It was against both these modes that Socrates and Plato contended; and to which Plato and Aristotle affixed the name as a term of reproach for a "man who employs what he knows to be fallacy, for the purpose of deceit and of getting money." (Grote, 'Hist. of Greece,' vol. v.) But the sophists were able to bear up against the judgment of philosophers, by having become the trainers of men for the active pursuits of life, and their influence over the multitude greatly exceeded that of the sages. Nor did they all, though they taught for money, teach fallacies merely; and the representations of them in the Dialogues of Plato must not be accepted as the truth with reference to them as a class. Socrates, Protagoras, and Prodicus, were stigmatised as sophists, but what we know of their doctrines and practice does not deserve any heavy condemnation. No doubt, in numerous instances the sophists, like the schoolmen of the middle ages, indulged in subtleties and evasions which were dishonest, trivial, and often ridiculous; but, as Ritter says ('Geschichte der Philosophie,' vol. i.), "It is not to be denied that the sophists contributed greatly to the perfection of prose; which was in itself a great benefit to philosophy. The sophists applied themselves to manifold arts of persuasion, and in their attacks upon each other, labouring to expose and lay bare the delusions of appearance, they acquired great nicety in the distinction of terms. Prodicus was celebrated for his skill in the distinctions of synonymous terms (as we learn from Plato, who ridicules him for it, (Protag. p. 337; Crat. p. 384); but Prodicus is honourably mentioned by him (Euthyd. p. 277-305). The sophisms turning upon the words 'to learn,' 'to understand,' 'to know,' also contributed to the more accurate knowledge of these terms. The very circumstance that their rules were intended to be subservient to the ends of fallacy and deception, must have afforded a stronger motive to the philosophical spirit to bring under investigation the true forms of thought and expression which had been neglected by earlier philosophers; and accordingly we find that they occupied much of the attention of Socrates."

SOPRA'NO (Italian), the highest of the various voices; the treble. [Voice.]

SORBIN. [Sugar.]

SORBINIC ACID. [Sugar.]

SORITES. A name given to any chain of premises, more than two in number, from which a conclusion follows. As, Every A is B, Every B is C, Every C is D, Every D is E, therefore, Every A is E.

SOTHIAC PERIOD. The ancient Egyptian year consisted only of 365 days, without any intercalation; and was divided into 12 months of 30 days each, with 5 days added at the end. (Herodotus, ii. 4.) The Scholiast on Aratus informs us that the priests were sworn never to alter this year. This oath, we may conjecture, only came into use after the discovery of the fact that a fraction of a day more would have been desirable to make the civil year conform to the sun. As long as 365 days was imagined to be the real year, it is not likely that they would have sworn each other to its observance; but if, after the discovery, a party were formed in favour of an alteration, the attempt to preserve the ancient institution by an oath would be almost a matter of course. Again, Diodorus Siculus (i. 50) says, that the Egyptians add five days and a quarter to the 360 days of their 12 months, which statement is generally supposed to refer to a more correct year which had been introduced among the people, while their religious festivals continued to be regulated by the old year. The propriety of this mode of reconciling the two authorities is made probable by the known existence of the Sothiac period (also called the Canicular year, Annus Magnus, &c., derived from Sothis, a name for the star Sirius) mentioned by Geminus, and also by Censorinus and Clement of Alexandria, from older writers. It is obvious that 1461 years of 365 days each make 1460 years of 365¼ days. This period of 1460 Julian years was the Sothiac period. It is impossible to fix any time at which this period was introduced, or to say whether, during its existence as a recognised cycle, it had time to run its whole career. Had it been a real cycle of experiment, it must be imagined that it would have been found to be wrong, to the extent of requiring an addition to the oath; for 1508 real years is nearer to the time in which a year of 365 days would have its beginning in all the seasons successively, and recommence the same process. It is obvious that such a cycle of recurrence was the intention of the Egyptians in constructing the period: their vague year (*annus vagus*) of 365 days, combined with their nearly fixed festivals, depending upon the heliacal rising of Sirius, made the latter take all consecutive positions among the months of the former, gradually falling later and later. Again, if the Egyptians had really gone through a whole recorded period, it is difficult to see how they would avoid discovering that another cycle would be necessary. In the time of their ancient kings the heliacal rising of Sirius would have advanced, by the precession of the equinoxes, about 12 days in one Sothiac period. The beginning of the vague year (365 days) was continually falling back; so that if at the beginning of a period they had noted the day of their vague year on which the equinox fell, and also the day on which Sirius rose heliacally, they would have found that the latter came again to the same day of the vague year fifty years, or thereabouts, before the equinox was similarly restored. This, so far as the star was concerned, would fit their erroneous period very well (1460 instead of 1508); but it is difficult to suppose that astronomers who had discovered the odd quarter of a day which the year requires, should not know within 12 days the time of the equinox.

The epoch of commencement of a Sothiac period is not well determined and only from comparatively modern writers. Censorinus asserts that the consulship of Ulpius and Pontianus (usually placed in A.D. 238) was in the hundredth year of such a period: accordingly B.C. 1322 was the beginning of the preceding period. Clement of Alexandria says that the period began 345 years after the migration of the Israelites from Egypt, a date which differs considerably from that of Censorinus, according to modern chronologers. The point is however of no importance, as no dates were ever recorded in written history by means of Sothiac periods.

SOTIES, or SOTTISES. [Drama; *French Drama.*]

SOULS, CURE OF. [Benefice.]

SOUND. For the various divisions of this great subject we must refer to Acoustics; Echo; Vibrations; Pipe; Scale; &c.; also to the various articles on Music and its theory.

SOUND BOARDS. The boards which are used in floors for the purpose of intercepting the passage of sound between the various storeys of a building, are known amongst builders by the name of *sound boards*. They are introduced in double floors (that is to say, in floors formed by separate systems of joists for the ceiling and for the floor-boards), immediately upon the ceiling-joists; and in single floors they are executed in short lengths, laid upon fillets, nailed on the sides of the deep joists. Upon these boards light plaster, or lime rubbish, or other material able to arrest the passage of the sound waves is laid, and the ordinary floor-boards are then nailed over the whole. Sometimes a mixture of lime and hair is laid upon sound boards as the "pugging material," to use the workman's phrase; and in others, plaster of Paris is used; but it must be observed, in either of these cases, that if the ceiling and the floor-boards should be closed before the moisture of the lime and hair, or of the plaster, has been allowed to evaporate, there is great danger of its producing dry-rot in the timbers. Indeed, whenever sound boarding is used, great precautions must be taken to ensure that no sappy wood be employed; and that the work should be allowed sufficient time to dry. In framed floors it is more easy to secure these conditions than it is in single ones, or at any rate it is more easy to establish a ventilation above and below sound boarding laid upon the top of the lower range of joists, as in the former case, than it is in the case of the boards laid between the single joists.

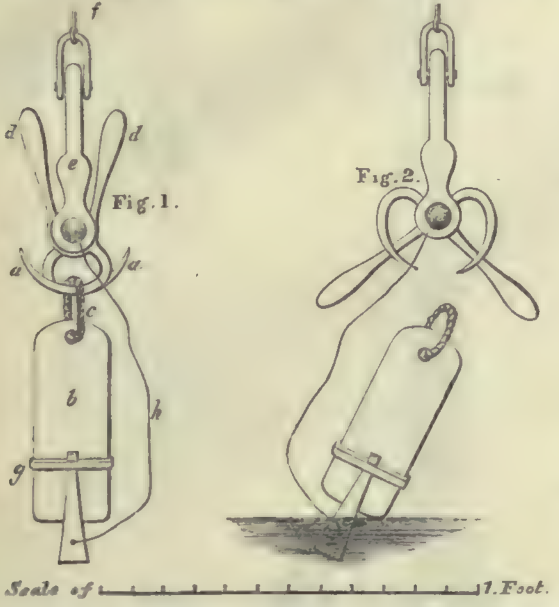
SOUNDINGS, DEEP SEA. Under the word Lead-line a general description has been given of the process of sounding in anchorages and moderate depths upon the coast. Deep-sea sounding requires totally different apparatus. Prior to about 1850, the question of deep-sea sounding was purely geographical and physical. To know the extreme depths of the ocean was but the natural march of that progress which had measured arcs of the meridian, and obtained the altitudes of the highest mountains on the face of the globe; and to descend to the mysteries of the earth's submerged surface, was but the obvious consequence of that insatiable desire for investigation which seems to characterise the minds of men of this particular epoch. But it is no longer a purely scientific question, since it has become a matter of urgent necessity to find, at the bottom of the ocean, a rest for the telegraph-wire.

With the exception of a few spirited researches, chiefly of a private character, little in the way of systematic soundings had been accomplished; though we must not overlook the advantages which deep-sea sounding received from the investigations ordered by Congress in 1849. The conduct of further and more elaborate experiments was confided to Lieutenant Maury, U.S.N., who was empowered by the Congress of the United States of America to equip a small schooner of 100 tons called the Fancy, for various scientific purposes; among them it was specially required that her commander, Lieutenant J. C. Walsh, U.S.N., should attempt to reach the bottom of the sea once in every 200 miles in crossing the Atlantic. Up to this time no particular apparatus for taking deep soundings had been in use: the ordinary round shot slung with strips of canvas was the usual means employed. It was found extremely difficult to determine in some cases the period at which the shot reached the bottom; the weight of some thousands of fathoms of line, and the influences of current and drifting of the vessel, rendered the exact depth attained only appreciable by long experience. The Fancy was, moreover, found too small a vessel for the purpose; the result, however, of the cruise reflects great credit on the commander, since he established the fact, that in some places the depth of ocean was more than 5700 fathoms, or was above six English miles! thus exceeding the height of the most lofty known mountain. This was the greatest depth that had been measured, without finding the bottom, and was attained on the 15th November, 1849, latitude 31° 59′ N., and longitude 58° 43′ W. The time used in the descent of the line to this enormous depth was only 1½ hour, but the line at last broke at the reel, losing the whole 5700 fathoms. We are assured by Lieutenant Maury, that the descent of the sounding line was accomplished without any jerks or checks, beyond those of the friction bands to give uniformity to the descent, so that the weight could not have touched the bottom, and was a fair straight up and down experiment. In this memorable sounding, the lead had a Stellwagen cone fitted to it, and a small apparatus weighing 6 lbs., for ascertaining the depth reached. The line was of steel wire of the best English manufacture. In May, 1850, the United States again determined on exploring the deep sea. Considerable attention was paid to every requisite, and the Albany, Captain Platt, was next equipped for this service; the principal locality of her observations was to be the Caribbean Sea. Instead of steel wire, this ship was fitted with about 40,000 fathoms of twine, weighing about 150 fathoms to the pound. This was usually attached to a 32 lb. shot, which was allowed in its descent to take the turn from the reel without control. After various failures, and the loss of much line and several shot, a useful list of soundings was obtained;—and which are described in Lieutenant Maury's work. The principal result of these experiments was the proving that in no part of the Gulf of Mexico is the depth greater than 1000 fathoms. It became evident, however, that with a *fixed* weight, it is extremely difficult to determine the exact depth when the bight of the line is swept off by an under-current, which, even when the shot rests upon the ground, continues to take the line from the reel with scarcely diminished velocity. This would have a general tendency to give exaggerated depths.

In May, 1851, another United States ship, the John Adams, renewed the soundings of the Atlantic, and accomplished the greatest deep-sea sounding which had as yet been obtained. The bottom was found in latitude 32° 6′ N., and longitude 44° 47′ W., at 5500 fathoms (Lieutenant Walsh, in the Fancy, had reached 5700 fathoms, but found no bottom). In this great sounding two 32 lb. shot were used, which, together with the 5500 fathoms of line, were lost on attempting to recover them:—correcting for drift, the actual depth is estimated by Captain Barron, her commander, at 4825 fathoms, or about 5½ English miles.

It is unnecessary to follow up these observations in detail. The experience gained in them led to various contrivances whereby the saving of the line at the expense of the shot might be effected. In the Dolphin, U.S.N., an improvement was made in having shot so cast as to slide upon an iron rod. Upon the latter touching the bottom, the shot released itself, and the line and rod were more easily recovered.

A great advantage over the rod and shot was gained by the invention of a kind of double claw, acting somewhat upon the principle of that used for detaching the monkey of a pile-driving machine. It was invented by a blacksmith of H.M.S. Spitfire in 1851, named Carmelo Bonnici, a Maltese. Captain Spratt, R.N., who commanded the Spitfire, introduced it to public notice in the 'Nautical Magazine' for 1856.



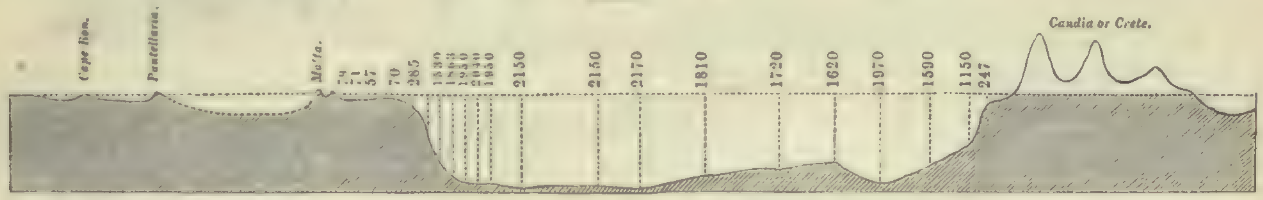
As the increasing demand for submarine telegraphs will much extend the work of deep-sea sounding, we give a few diagrams of the means employed in that interesting operation, as well as some sections of the sea bed, carefully drawn to a scale, and, in order to facilitate comparisons, each of them has the horizontal scale in proportion to the vertical as 30 to 1.

Bonnici's claw, as it is called, consists of two metal hooks of peculiar shape working on a pin, so that on any weight being attached it clasps and sustains a wire or line; its great advantage being that any kind of sinker may be used with it, namely, either a shot or a pig of iron, or, on the want of these, a piece of heavy stone. In the above figures, No. 1 shows the outline of the apparatus when in course of descent, *a a* being the claws hooked into a rope-grummet, *c*, suspending a weight, *b*; the arms, *d d*, of the claws lie close to the link *e*, to which is fastened the sounding-line *f*, and the whole outline is such as to favour the descent of the apparatus; but the moment the lower portion touches the bottom, the arms *d d* being relieved of the weight of the sinker, drop, as in *fig.* 2, and the claws detach themselves from the grummet, and the weight is left at the bottom.

It will be noticed that a piece projects beyond the underpart of the sinker which, among various contrivances, is loosely tied with string, *g*, to the body of the sinker: this has a hollow armed with tallow in the end, to bring up indications of the nature of the bottom bed, as in the ordinary hand-lead. On the sinker being detached from the apparatus, a small string, *h*, attached to the link of the instrument draws this clear of the mass of the sinker, and it is hauled up with the line.

This was a great step towards a better system, but it required considerable care in *setting* the instrument, so as to insure the ready detachment of the weight on reaching the sea-bottom. Captain Spratt, however, made excellent use of it. He was engaged in sounding upon an extensive scale in the Mediterranean. In the accompanying section it will be seen that his greatest depth was 2170 fathoms, or nearly 2½ miles: this was obtained in about lat. 35° 30′ N., and long. 18° 45′ E. It shows that eastward of Malta there exists a small plateau, having on it from 70 to 80 fathoms water, but that 50 or 60 miles from Malta, in the same direction, there is an enormous submarine escarpment of some 2000 fathoms, or 2¼ English miles.

Section 1.

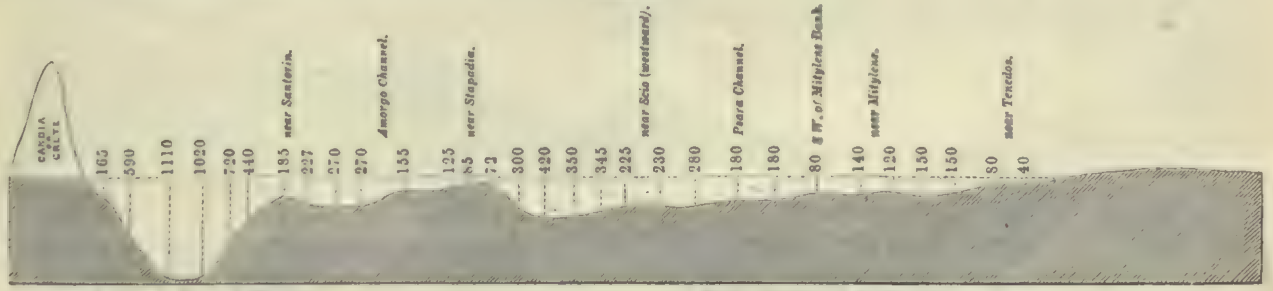


Tunis to Candia or Crete.

Scale—Horizontal 136,000 fathoms } to one inch, or 30 to 1.
Vertical 4,533 „

In the following section we see that the bed of the Mediterranean rises as we proceed northward in the Archipelago, the deepest water (after passing the deeps about Candia) being 420 fathoms, and then gradually shallowing.

Section 2.



Candia, or Crete, to Tenedos.

Scale—Horizontal 60,000 fathoms } to one inch, or 30 to 1.
Vertical 2,000 „

In 1857, Captain T. Mansell, in H.M.S. Tartarus, was occupied in sounding between Alexandria, Rhodes, and Smyrna. He also used Bonnici's claw, but had in addition Lieutenant Brooke's (U.S.N.) apparatus in which had been substituted a conical mass of iron, sliding on a rod. This is an exceedingly simple and ingenious plan, but has been surpassed by improvements yet to be described. Captain Mansell seems to have given each of these instruments a fair trial in the Mediterranean, and records his decided preference for the Bonnici claw. The following will explain Brooke's apparatus. It is remarkable as the one used in discovering the plateau existing between Ireland and Newfoundland.

In *fig.* 3 (col. 683), *a a* are arms working loosely upon a pin at *b*, connecting them with the rod *c*. The sounding line is attached at *d* to the bridle connecting the upper ends of the two arms. The conical weight sliding upon the bar, is held in its position during the operation of sounding by a looped line passing under the base of the cone, and loosely hung on the spurs, *e e*, of the arms; immediately on the sounding-line being relieved of the weight of the apparatus by the latter touching the ground, the arms drop into the position shown by dotted lines, and the loops slip off the spurs, thus detaching the cone altogether, which slips off the bar. But here is supposed to be a defect in the apparatus, inasmuch as the force necessary to draw the rod from the aperture of the cone, when in a much inclined position upon rocky bottom, is found enough to break the line at great depths.

Another excellent form of simple apparatus was invented by Mr. Skead, R.N., Master of H.M.S. Tartarus, and found by Captain Spratt to answer admirably in comparatively shallow water. *Fig.* 4, is a sketch of it. The sounding-line is attached to a small metal

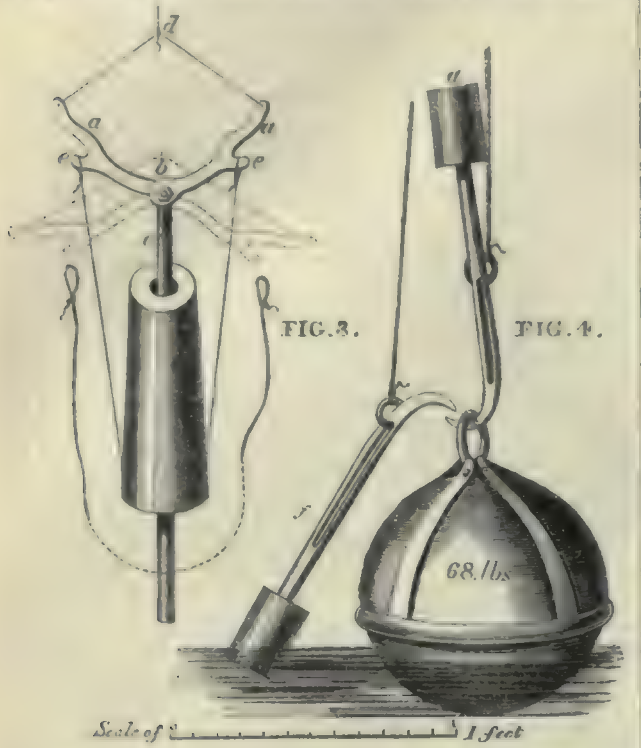


FIG. 3.

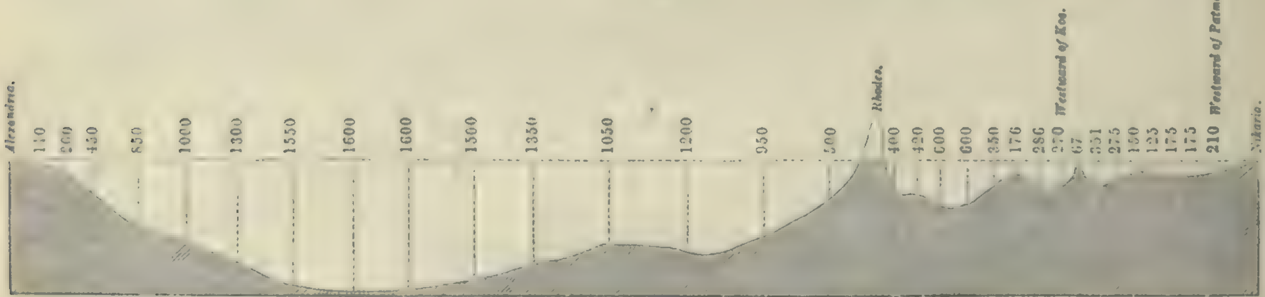
FIG. 4.

ring, which slides in a groove in a bar of quarter-inch iron, and 12 inches in length, having a small hook at one end, and a weight at the other, **hollowed and jagged so as to bring up any portion of the bottom. This can be used with either shot or pig-iron, and on reaching the ground the weight *a* descends and unhooks the sinker, which being left at the bottom the simple apparatus is easily recovered without much strain on the sounding-line. The position of the hook at the moment of detachment from the weight is shown at *f*.**

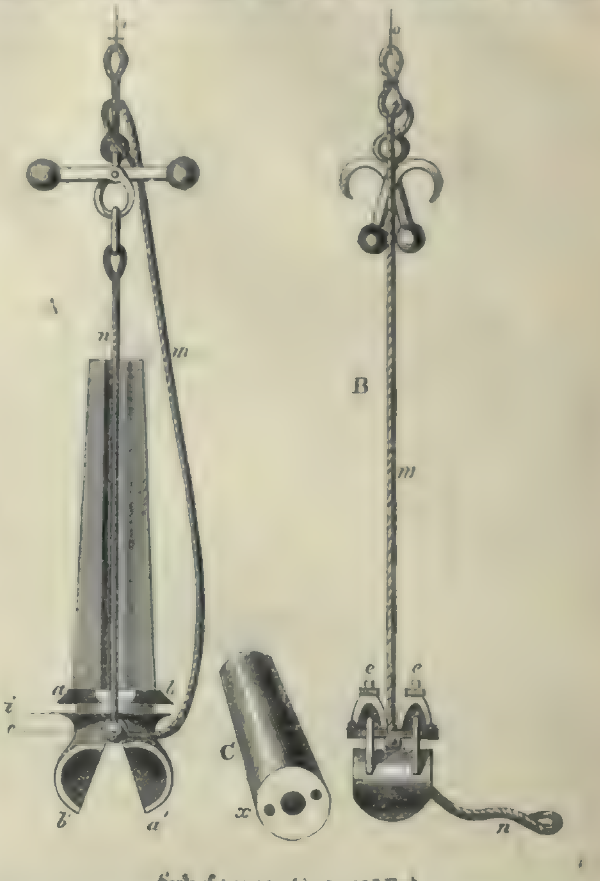
The result of Captain Mansell's labours can be best explained by the following section (3).

Section 3.



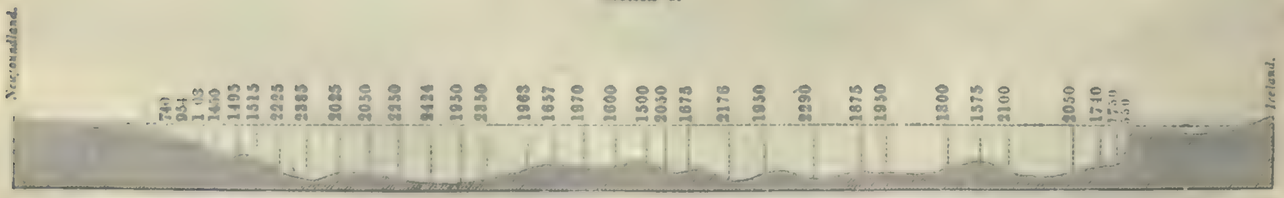
Alexandria to Nikaria.

Scale—Horizontal 71,000 fathoms } to one inch, or 30 to 1.
Vertical 2,367 „



In 1857, Lieutenant (now Commander) Dayman, R.N., was ordered to check the deep soundings which had been taken by the Arctic between Europe and North America, preparatory to the laying of the Atlantic electric cable. [TELEGRAPH, SUBMARINE]. The following (4) is a section published by him, and shows in a remarkably satisfactory manner that the examination of the bed of the ocean at any part of the globe is probably within the power of man even with existing apparatus. In no part of the Atlantic under his observation did he find the depth beyond 2424 fathoms, or about 2¾ miles.

Section 4.



Newfoundland to Ireland.

Scale—Horizontal 254,160 fathoms } to one inch, or 30 to 1.
Vertical 8,472 „

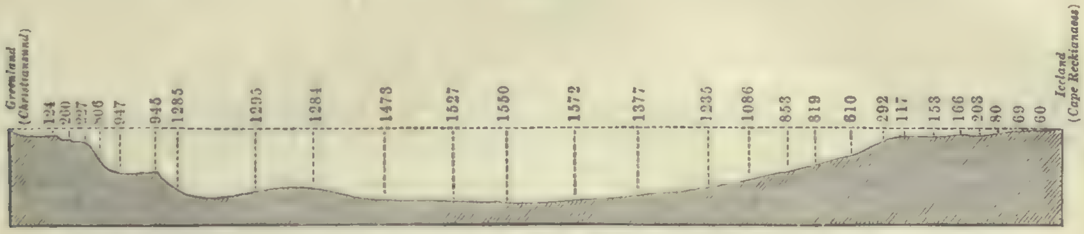
It is unnecessary to mention more than the leading facts connected with deep sea soundings. It becomes, however, an act of justice to remark that the United States' Government, who took the lead in sounding the Atlantic, are doing the same in the Pacific. The United States' schooner Fennimore Cooper was commissioned by Lieutenant Brooke (the experienced officer who invented the sounding apparatus bearing his name) for the purpose.

The only other deep sea soundings which we shall mention are those by Captain Sir F. L. McClintock, of H.M.S. Bulldog, in the Northern Ocean in 1860. It has been shown that much of the success of previous experimenters had depended on the instruments in use. One great object also had been to collect as much of the sea bed at each operation of sounding as possible. Up to 1860 very many contrivances had been in use to effect this, with various results. Captain McClintock had been provided with a modified form of Brooke's machine, but it did not answer his expectations. Much attention was given to improvements by Mr. Roughton, his chief engineer, and Mr. Steil, his assistant; also by Dr. Wallich, naturalist to the ship; but Mr. Steil succeeded admirably in contriving a double-scoop machine wherewith to bring up a considerable quantity of the sea bed. It will be henceforward known as the "Bulldog sounding machine," and is of the form shown in col. 684.

In this, Lieutenant Brooke's plan of a hollow sinker is combined with Bonnici's claws, but the section of its scoop requires some little explanation. The two parts *a a′* and *b b′* move like shears on the pin, *c*, in *fig.* A. Another view of them is in *fig.* B, in which *e e* are two studs, which fit the two holes loosely in the cone, as in C at *x*. When the cone is descending it rests on these two studs and collars, being steadied by the line in A and B marked *n*. A strong india-rubber band, *i*, is attached, so that on the apparatus reaching the ground, the sounding-line, *o*, being relieved from the weight, allows the claws to fall open, as in B, and the part of the line *n*, being released, the cone tilts off the studs, *e e*, and falls, remaining on the ground; the part of the line *n*, unreeving through it, as *n* in B, and the claws and scoop being secured to the part *m*, are hauled to the surface; the removal of the cone from *e e* allowing the india-rubber bands to compress and close the scoops while in the ground, inclosing about 4 lbs. of the bottom of the sea.

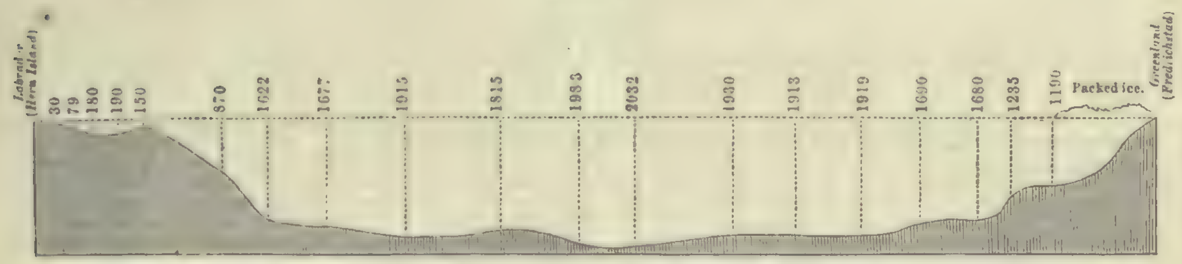
Captain McClintock's results will be best understood by the following sections of his principal soundings.

Section 5.



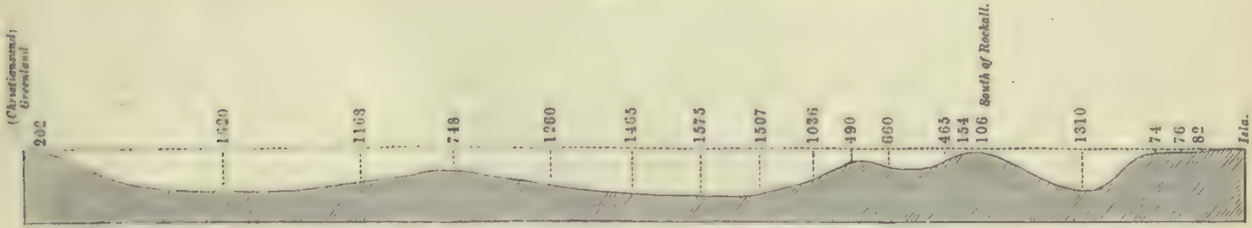
Greenland to Iceland. Scale—Horizontal 120,000 fathoms / Vertical 4,000 ,, } to one inch, or 30 to 1.

Section 6.



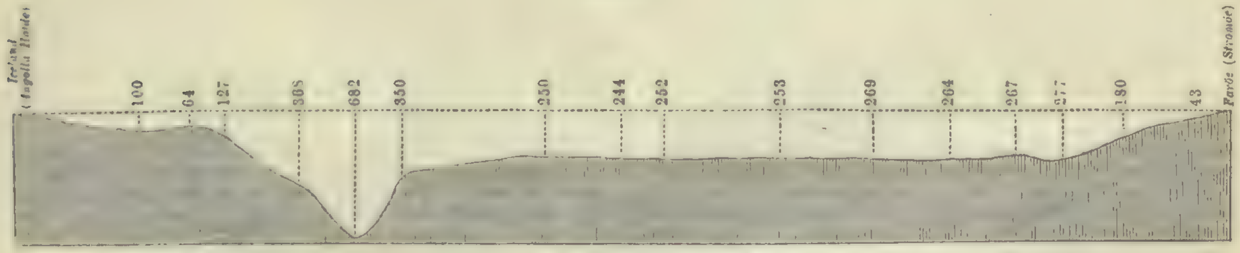
Labrador to Greenland. Scale—Horizontal 90,000 fathoms / Vertical 3,000 ,, } to one inch, or 30 to 1.

Section 7.



Greenland to Isla. Scale—Horizontal 180,000 fathoms / Vertical 6,000 ,, } to one inch, or 30 to 1.

Section 8.



Iceland to Faröe. Scale—Horizontal 30,000 fathoms / Vertical 1,000 ,, } to one inch, or 30 to 1.

All the above sectional diagrams are upon the same relative scale, namely, 30 to 1, and each is referred to the inch. Much valuable information on deep sea sounding may be obtained from Maury's works on the Physical Geography of the Sea: and many very useful details are recorded in the pages of the 'Nautical Magazine.' [SEA.]

SOUNDS, HARMONIC. [HARMONICS; TEMPERAMENT; ACOUSTICS.]

SOUTH KENSINGTON MUSEUM. The formation of a national Museum of Ornamental Art was commenced on a very small scale in 1838. Originally intended merely as an adjunct to the Central School of Design, its progress was comparatively slow. By the Great Exhibition of 1851, however, not only was attention directed strongly to the necessity of forming a more comprehensive museum for the especial use of manufacturers and art workmen, and which should at the same time serve to interest and instruct the public generally; but it was also seen that the exhibition afforded a singularly favourable opportunity for securing the nucleus of such a museum. A selection of objects was accordingly made from the Indian, Continental, and British sections, and along with the articles previously purchased for the Museum of the Schools of Design, exhibited to the public in a suite of rooms appropriated to the purpose in Marlborough House. The Museum of Ornamental Art thus formed, was in the following years considerably increased by the purchase of the collection of porcelain and pottery of Mr. Bandinell, and by extensive purchases made at the Bernal sale. In 1857 the museum, which had been placed under the Department of Science and Art [Science and Art, Department of], was removed to the iron building erected by the Commissioners of the Exhibition of 1851, on the ground purchased by them at South Kensington. The Museum of Ornamental Art has since been very largely increased, and other collections have been added to it, and the whole has been incorporated into what is officially designated the South Kensington Museum of Science and Art; buildings of a permanent character having been at different times added to the original iron structure to meet the growing requirements of the case.

As at present constituted, the South Kensington Museum consists of three distinct divisions; those, namely, of Ornamental Art; of Fine Art; and of Science. In the Companion to the Almanac for 1861 is given a full analysis of the Museum, to which we refer for further details, contenting ourselves with giving here a brief statement of its general character.

The *Museum of Ornamental Art*, as it formed the foundation, may still be regarded as the distinctive feature, of the South Kensington Museum. Although intended primarily to aid the Schools of Design, and to improve the manufactures of the country, it has of late years, in a great measure, to use the words of its director, "settled itself into Mediæval Art," or rather the art of the mediæval and renaissance periods. Within these limits it is, however, very comprehensive in its range, and articles have been sought out for purchase with great industry and judgment. The Museum of Ornamental Art is arranged in eighteen classes:—(1) Sculpture, in which are many exquisite specimens of Italian architectural sculpture of the renaissance period, carvings in wood, ivory, bone, &c., including some admirable works by Fiammingo, with some important examples of artists of an earlier period; bronzes and terra-cottas and models, among which are some by Michel Angelo. (2) Glyptic and Numismatic Art, including gems, medals, and seals. (3) Mosaics, Marquetry, &c. (4) Painting, almost exclusively of a decorative character. (5) Japanned or Lacquered Work. (6) Glass Painting—comprising Italian, German, and Flemish examples from the 13th century to the decline of the art, with a few of recent execution. (7) Enamels on Metal, an extremely choice and valuable collection, especially rich in early German champlevé works, and the much-prized Limoges enamels, and including also some interesting specimens of modern Indian and Chinese work. (8) Pottery, as a whole, one of the finest collections in Europe, including a few examples of Egyptian, Greek, Etruscan, and other antique ware; Hispano-Moresco ware; early Italian enamelled and incised ware; an almost matchless collection of Gubbio and other lustred wares, and Majolica of the various Italian manufactories; modern reproductions; Persian painted ware; Morocco enamelled earthenware; Palissy, Nevers, and other French glazed and enamelled earthenware; Delft, old German, Dutch, and Flemish stoneware; old Saxon red stoneware; Hindoo and other Oriental earthenware; Oriental porcelain (China and Japan); Dresden and other German porcelain; old Sèvres; modern Sèvres; French porcelain of various manufactories; Italian, Dutch, Spanish, and Portuguese, Swiss, Danish, and Russian 18th century porcelain; old English earthenware, stoneware, and porcelain, &c., of all the principal varieties (including a fine collection of old Wedgwood), and English and Foreign modern porcelain, earthenware, biscuit, Parian, &c. (9) Glass Manufactures, including a very choice selection of old Venetian, German, and French glass, and a few examples of modern glass, chiefly French and English. (10) Works in Metal, comprising wrought-iron coffers, &c.; locksmith's work; instruments; knives, forks, spoons, &c.; firedogs and stoves; candlesticks, chandeliers, &c.; antique Greek and Roman ornamental bronzes; Oriental bronze vessels; metal household utensils; mediæval ecclesiastical utensils; modern bronze vessels; goldsmiths' work both ancient and modern; damascene work; nielli. (11) Watch and Clock Work. (12) Jewellery and personal ornaments in the precious metals, ancient, mediæval, modern, and Oriental. (13) Arms, Armour, and Accoutrements. (14) Furniture, Upholstery, &c., including a singularly interesting variety of old Italian cassone or marriage chests, carved cabinets, mirrors, &c. (15) Leather Work. (16) Basket Work. (17) Textile Fabrics,—as might be anticipated in a British Museum of Ornamental Art, the most extensive collection of the kind extant. (18) Bookbinding and Book Decoration generally.

The Fine Arts Division comprises the Sheepshanks' collection of 234 modern oil paintings; a small collection of drawings and sketches also presented to the nation by Mr. Sheepshanks; and a collection of 50 water-colour paintings, the gift of Mrs. Ellison of Sudbrooke, to which other drawings have been added by purchase: these collections are more particularly noticed under National Gallery.

The *Science Division* consists of—1. An Educational Collection, in which are brought together, models of schools, school-fittings, school-books (and a reading-room, in which to examine them) maps and diagrams, philosophical instruments, &c., in fact, as far as practicable, whatever may serve to guide or assist those engaged in teaching. 2. Collection of Animal Products. 3. Food Collections— in which are shown the chemical compositions of the various substances used as food. 4. Structural Museum, in which are collected the materials employed in building, &c.

These form the Museum proper; but to them are to be added other collections which are placed in the same building, though they do not belong to the Department of Science and Art. They consist of the British pictures belonging to the National Gallery, which are placed here temporarily [National Gallery]: collections of architectural casts belonging to the Architectural Museum Association and the Royal Academy; a small collection of modern sculpture, chiefly casts, and the Patent Museum belonging to the Commissioners of Patents. Certain rooms are also set apart for the reception for a limited time of choice collections of articles of ornamental art belonging to private individuals; and there are now usually five or six of these "Loan Collections" on view here at one time, containing commonly many specimens of great interest and value.

The total cost of the South Kensington Museum up to July 1860, was 167,000*l.*, including everything except management, the annual expenditure on which is about 7000*l.* Of the above sum the land cost 60,000*l.*, the buildings 54,536*l.*, the collections 58,269*l.* The value of the private gifts to the Museum, including the Sheepshanks and Ellison collections of paintings, is estimated by the director at upwards of 88,000*l.* The permanent buildings which have been erected are intended to form part of a spacious structure which is to cover an area of above ten acres, and to supply all the requirements of the Department at South Kensington. [Science and Art, Department of.] In its main features the building is intended to consist of a centre and two great projecting wings, the fronts of which are to be connected by an open corridor. In the centre will be the Lecture Theatre, Art Training Schools, &c. The eastern wing will be appropriated to the Art-collections; the western to the Educational collections, Art-Library, offices, residences, &c. The extreme length (facing Cromwell Road) will exceed 700 feet; the extreme depth (or western façade) 650 feet, but the site is very irregular. The design is by Captain Fowke, the official architect and engineer to the Museum; the total cost is estimated at 214,000*l.*, but at present only the eastern wing is in course of erection.

All the collections are open free to the public on Mondays, Tuesdays, and Saturdays in each week; on the other days (being "students' days") the public are admitted on payment of 6*d.* each person. The collections are also opened to the public free on the first two evenings of the week—an innovation which has proved exceedingly popular. To the Art Library—a very excellent one—though formed primarily for the students, any person is admitted on payment of a trifling fee.

SOVEREIGN. [Money.]

SOVEREIGNTY. *Supranus* is a low Latin word, formed from *supra*, like *subtranus*, another low Latin word, formed from *subtra*. (Ducange *in vv.*) These words, however, though they do not belong to classical Latinity, are formed according to the same analogy as the classical word *supernus* from *super*. From *supranus* have been derived the Italian *soprano* or *sovrano*, and the French *souverain*, from the latter of which has been borrowed the English word *sovereign*. In the old English writers the word is correctly spelt *soverain* or *soverein* (Richardson *in v.*); the received orthography seems to be founded on the erroneous supposition that the last syllable of the word is connected with *reign*, *regnum*. Milton spells the word *sovran*, deriving it from the Italian; but it passed into our language from the French.

Having explained the etymology of the word *sovereign*, with its derivative, *sovereignty*, we proceed to consider the meaning of the term sovereignty as it is understood by political and juridical writers.

In every society not being in a state of nature or a state of anarchy [Anarchy; Social Contract], some person or persons must possess the supreme or *sovereign* power.

The marks by which the possession of the sovereign power may be distinguished are mainly two, the one positive and the other negative; namely:—

1. A habit of obedience to some determinate person or persons, by the community which he or they assume to govern.

2. The absence of a habit of obedience, on the part of the same person or persons, to any person or government.

Whenever these two marks meet in any person or body of persons, such person or body possesses the sovereign power; on the other hand, if either of the two marks be wanting, the person or body is not sovereign. For example, the local government of Jamaica or Canada, being in the habit of obeying the English parliament, is not a sovereign or supreme government; whereas the governments of the smaller German states, although they may occasionally defer to the wishes of Austria or Prussia, are not in a habit of obedience to these or any other states, and therefore are sovereign governments. Again, a body of persons calling themselves a government, but unable, through their weakness, to secure the habitual obedience of the people, are not sovereign, and would not be recognised as a sovereign government by foreign states.

Inasmuch as it is impossible to fix the precise moment at which a habit of obedience to a foreign government ceases, it is difficult for foreign states to determine when they will recognise the sovereignty of a territory, once dependent, which has achieved its independence.

The sovereign powers include all the powers which can be exercised by a government. They include the legislative power, the executive power, the power of making *privilegia* [LAW; LEGISLATION], the power of declaring peace and war, and of concluding treaties with foreign states, the power of making contracts with private individuals, and the power of instituting inquiries.

Sovereign power abstractedly is unlimited by any legal check or control. The securities for its beneficial exercise are derived exclusively from the balance of interests and the influence of public opinion.

Sovereign or supreme governments are divided into MONARCHIES and REPUBLICS; and REPUBLICS are divided into ARISTOCRACIES and DEMOCRACIES.

It is commonly, but erroneously, thought that the sovereignty resides in every person who bears the name of *king;* in other words, that every king is a monarch. Accordingly those kingdoms in which the king is not strictly a monarch are called "limited monarchies;" and the king is supposed to be a sovereign whose power is checked or controlled by certain popular bodies; whereas, in truth, the sovereignty is divided between the king and the popular body, and the former does not possess the entire sovereignty. This subject is further explained in KING, MONARCHY, and ROYALTY.

The subject of sovereignty is well explained in Mr. Austin's 'Province of Jurisprudence determined.' The received doctrines upon the subject will likewise be found in the treatises on international law. The 'Leviathan' of Hobbes contains a view of the nature of sovereignty, which has been often misunderstood and misrepresented by later writers.

SOWING AND SOWING-MACHINES. The sowing of the seed has always been looked upon as one of the most important operations of husbandry. Much of the success of the future crops depends on the time and the mode in which the seed is committed to the earth. After the land has been well prepared by judicious tillage and manuring, many accidents and circumstances may disappoint the hope of the farmer, and the crop may be scanty or fail altogether. The weather and the seasons are not under his control, and he must submit to the dispensations of Providence with pious resignation; but much also depends on his own judgment and skill. If he selects the best seeds, chooses the proper season for sowing them, and has them carefully distributed and properly covered with earth, as their nature requires for the most perfect germination, and thus also protects them from the voracity of birds or insects, he will have a much greater prospect of success, under all circumstances, than if he were careless or negligent.

The most common mode of sowing the seed is by scattering it as evenly as possible over the ploughed surface, as it lies in ridges from the plough. The harrows follow, and crumbling down the ridges, cover the seed which has fallen in the hollows between them. It requires an experienced sower to scatter the exact quantity over a given surface, without crowding the seed in one spot, and allowing too great intervals in another. Hence the farmer who does not himself sow the seed, invariably chooses the most experienced and skilful labourer to perform this work. Notwithstanding every care and attention on the part of the farmer or master, the labourer will often relax and become careless, and the result appears only when it is too late to remedy it. This has given rise to the various attempts which have been made to invent machines for sowing the seed, such as should insure perfect regularity. Of some of these we will now give a short account.

One of the simplest of these machines consisted in a hollow cylinder, with one or more rows of holes in a line parallel to the axis. These holes can be stopped in part if required. The seed is put into the cylinder, the length of which is equal to the width of the land, or stitch, which it is desired to sow at a time. By shaking this when held horizontally and at right angles to the path of the sower, the seed is scattered with considerable regularity: one inconvenience of this instrument is that it requires to be filled frequently, and that much still depends on the attention of the operator. Accordingly it was very soon laid by. The idea, however, was followed up and improved upon in the *sowing-barrow,* an instrument still extensively used for sowing grass-seeds. It consists of a wooden trough placed on the frame of a light wheelbarrow. An iron spindle, furnished with circular brushes at regular intervals, runs the whole length of the trough, and is turned by means of simple machinery connected with the wheel. Opposite each brush is a brass plate, with holes of different sizes, which can be partly closed by means of a circular slide. According to the size of the seed to be sown and the quantity to be scattered, the holes are opened or shut. The seed is put into the trough, which has a cover or lid; and by merely wheeling the barrow in a straight line, a breadth is sown equal to the length of the trough, usually 12 or 15 feet. But this machine cannot conveniently be used in windy weather, which disperses the seeds irregularly; and it is very little superior to sowing by the hand, except in the case of small seeds, which cannot so well be spread evenly by the hand.

The drill husbandry has suggested other more complicated machines, of which some account will be found in the article DRILL. The principle of these is to deliver the seed by means of funnels, each corresponding to a small furrow made by a coulter placed immediately before the funnel; and some of these machines perform the work very regularly and satisfactorily. As the inequalities of the ground require that the coulters should move up or down, to allow for these inequalities, the seed cannot be accurately deposited at a given depth; and some further improvement in the mode of drilling is yet desirable, though much has been effected. The patent lever-drill in common use is very imperfect in its work, and the remedy lies in the greater attention to the preparation of the surface. When this is effected, the levers may be set aside, and a much simpler drill, such as was used at first, may replace it. The object is to make furrows of equal depth in which to deposit the seed, and to cover this uniformly. The land must consequently be more carefully prepared by repeated harrowing and rolling, till the surface resembles the seed-beds in a garden. A simple drill, which makes equidistant furrows at a given depth, in which the seed drops regularly, will then do better work than a more complicated machine; but if still greater accuracy and perfection are desired, the dibble must be had recourse to. No one will deny that seed deposited by means of a dibble is distributed more equally and covered with a more equal depth of soil than by any other means, and that there is a great economy of seed in this mode of sowing; but the slowness of the operation, and the number of hands it would require to dibble all the seed on a large farm, have prevented its being very generally adopted. [ARABLE LAND.] Many attempts have been made to invent machines to imitate the work done by hand in dibbling, but hitherto with no marked success, owing chiefly to the difficulty of clearing the dibbles from the adhering soil, and making a clean hole, and also of letting the seed fall exactly in the dibble-holes.

SOY, is obtained from the *Soja hispida,* or *Soja japonica* [SOJA, in NAT. HIST. DIV.] From the seeds of this leguminous plant, the Japanese prepare the sauce termed *Sooja,* which has been corrupted into *Soy.* The beans are boiled until the water is nearly evaporated, and they begin to burn; when they are taken from the fire, and placed in large wide-mouthed jars, exposed to the sun and air; water and a certain proportion of molasses or very brown sugar are added. These jars are stirred well every day, until the liquor and beans are completely mixed and fermented; the material is then strained, salted, and boiled, and skimmed until clarified. There are two or three qualities of soy. Japanese soy is much esteemed in China on account of the superior manner in which it is made. Soy is only sparingly used as a sauce in this country.

SOYMIDA. [SOYMIDA, in NAT. HIST. DIV.]

SPACE AND TIME (Mathematics). We do not here propose to enter into any discussion of the doctrines of psychologists as to the idea of space, or as to whether it be innate or acquired. Space and time are essential to thought, and are, come by the notions how we may, necessary attendants on our own consciousness of existence. It is possible for imagination to picture the annihilation of all things, itself included, or to fancy that it can form such a picture, which is the same thing; but what then would remain (in the thoughts)? Infinitely extended empty space, lasting through infinitely extended time. Existence of space and successions of existence we may defy the speculator to deprive himself of for one moment. The greatest proof we have of our ignorance of the Creator of all things is the absolute impossibility which we find of making the necessity of his existence as real a conception of our minds as that of space or time. The most religious man will read with pleasure a work on natural theology tending to prove that there must be a God; but who would bear ten pages of a serious attempt to demonstrate the existence of space and time?

In these ideas we have the foundation of the mathematical sciences; for from space follows form, which is the conception of the manner in which one part of space is separated from the rest, and from the investigation of forms arises geometry. Again, time is only apprehended by succession of events or ideas, and succession or repetition gives the notion of *numbering.* And though *collection* is sometimes stated to be the leading idea in *number,* yet it may be asserted that number in the last sense is not the object of arithmetic, except as furnishing the subject of numbering. The leading phrases of arithmetic suggest the idea of time, and are derived from it. How often is 2 contained in 12? Six times. The 2 presented to the thoughts at six different times is the mode in which the collection of 12 is counted by twos.

From both space and time we get the notion of direction, but in very different manners. The extremities of a portion of length give the idea of a point of space, a fundamental notion of an indivisible index of commencement or termination. The extremities of time give the notion of points of time, or indivisible portions of duration. No point of space contains any space; no point of time lasts any time. If we choose a point of space or a point of time, we can in our thoughts set out from the former in an infinite number of different ways; from the latter, in only two. This is the law of thought, upon which it is useless to speculate; but it is followed by important consequences. So long as algebra, the science of reasoning by symbols, was founded only on notions of arithmetic or succession, its ideas were not competent to furnish explanation to all the results of its mechanical processes. As soon as the same rules were transferred to ideas of space, or made to spring from geometrical explanations, the mysteries of that science gradually vanished.

From space and time, also, we get the idea of infinity, a subject which has been already treated [INFINITE]; but only in such a point of view as would meet the objections of those who cannot reason clearly on absolute infinity. That space and time are unbounded, is the simple consequence of their being necessary to our notion of the existence of anything: we speak of our conceptions of them. For if it could be imagined that *space ceased* at a certain boundary, it would be as easy to make it cease in our own neighbourhood; and if duration could be imagined to have an end, it would not be difficult to place ourselves in thought within five minutes of that end. The denial of the possibility of our approaching the boundary of space or time in our thoughts, is the same thing as the denial of the existence of such a boundary; and the notion of infinity becomes a relief from the incongruity of the attempt to conceive existence stripped of its essential conditions. But it might be asked why not, as to space at least, consider real existing extension, not as the object of our thoughts, but as it would exist if we were not alive to think? Is it, or is it not, physically possible to go on for ever in space? If a person could provide himself with an unlimited supply of motive-power, air, heat, food, &c., must we, or must we not, say that there is anything to hinder his travelling to all eternity? For ourselves, we should say there is clearly nothing to hinder; but of course we cannot appeal to experiment, and it may be only the impossibility of destroying our own conception of space which dictates an answer as to that external reality which, let metaphysicians say what they please, can always be established by a wave of the hand. We should have supposed that, mysterious as the connection may be between the external world and our impressions of it, the possibility of really infinite external space would be admitted by any one, unless he held the metaphysical system of Berkeley, which denies the necessity of any external substratum of our conceptions, and substitutes the direct agency of the Creator; and we should have thought it impossible to maintain the necessary finitude of *matter*, without also maintaining the same of real external space. Nevertheless, to show how differently these subjects strike different persons, we quote the following from a dissertation of an eminent writer:—"Every *real, existing, material* body must enjoy that indefeasible attribute of body—namely, *definite place*. Now place is defined by *direction* and *distance* from a fixed point. Every body, therefore, which does exist, exists at a certain definite distance from us, and at no other, either more or less. The distance of every individual body in the universe from us is therefore necessarily admitted to be finite." Now it will hardly be denied that the space which a body fills is as real and existent as the body itself, and this whether so occupied or not. Leave out the word *material* in the above, and for "body" read "part of space," and the argument remains as good as before, ending with a denial of the infinity of space. Every *assignable* body is at a finite distance from us; but this is an identical proposition contained in the meaning of the word assignable. But who is *therefore* to deny the following? Name any distance, however great; matter exists at still greater distances.

If we estimate the reality of a conception by its necessity, which is what we do when we settle the pre-eminence of space and time among our ideas, then it is certain that the conception of infinity is as real as that of space or time, being essentially united with them. Many mathematicians try to deny this, and substitute various modes of speaking to avoid the introduction of the idea. It is true that the notion of infinite is one which it is difficult to use without falling into error; a very good reason for avoiding it until the understanding has been well practised in mathematical deduction, but none for denying its existence. Why say that the notion of infinity arises from our not being able to assign a limit, when we know that we feel something more positive; when we are as certain as we are of any right to use the words *can* and *cannot*, that there *cannot be* a limit, to either space or time? Those who examine the views of different writers on the first principles of science see a great variety of modes of expression on this point, but a uniform practical use of nothing more than the *denial of finitude*, accompanied by the mere expression of *incapacity to attain infinity*; resolutely coupled, in many cases, with a determination not to allow any words capable of expressing the *absolute notion of infinity* which actually is before the thoughts. Now it should be the object of elementary writing, while guarding the avenues to error which branch in all directions from an improper use of the word infinite, to acknowledge the existence of the idea, and to make a gradual preparation for its correct and legitimate use. Both infinitely small and infinitely great ought to become terms which may be employed without fear; and the student who has been trained to the natural and healthy use of all his notions will in the end succeed better than the one who has had some of them tied up from the beginning because they are somewhat difficult or somewhat unsafe to use at first.

So soon as an attempt is made to fetter one branch of thought, the effect is sure to be immediately felt in others. The infinite divisibility of space is a truth of the same sort as its infinite extension. *Matter* may not be divisible without end, and the truths of modern chemistry would seem to show that there are ultimate particles inseparable by chemical, and still less by mechanical, means. But there is a solvent which everyone has it in his power to apply to space; it is the intuitive conviction that every portion of it, however small, except that ultimate notion which is called a point, is divisible into parts, which are themselves divisible into parts; a process which may be continued without end. Now, a person who trifles with the notion of infinite extension, and persuades himself that he has not the idea, will probably end by denying infinite diminution; and as motion, however small it may be, requires the succession of positions answering to an unlimited separation of the time of motion into parts, the next step will be to deny the infinite divisibility of time, and the possibility of motion, as commonly conceived. Change of place will be imagined to be physically impossible, if it be asserted that between the first and last positions there have been an infinite number of others; and the mind will be driven, in order to avoid the notion of infinity, into a sort of opinion that motion is a very large (but finite) number of annihilations and re-creations: annihilation in one spot, and re-creation a little farther on, without anything intermediate. This is no imaginary case; and it seems to us that when this theory of motion is once attained, nature has taken a satirical revenge for the attempt to smother her conceptions.

The errors which arise from the improper use of the notion of infinite, lie mostly in the idea that all that is proved of finite space or time must necessarily be true of the infinite. We pass over the error that all infinites must be equal, as being that of the merest beginner; there are enough remaining to claim great caution. The process adopted in the article INFINITE is perhaps the best way of habituating the young mind to the rigorous attainment of results, provided only that the understanding be duly apprised that such a course of proceeding is not pursued because there is *not* infinity, but because there *is*, and because the notion, though inevitable, is not easily used. The road need not be carried over any unsafe foundation; but that is no reason why the quicksand and the marsh should be left out of the map.

SPACES, in Music, the intervals between the five lines forming the staff. [STAFF.]

SPAHIS (or rather *Sipâhis*, from the Persian *sipah*, meaning a cavalry soldier), are a body of Turkish cavalry organised by Amurath I. (Múrad), who was also the founder of the Janizaries. Their number varied according to circumstances, but amounted sometimes to 20,000. They enjoyed many privileges in common with the Janizaries. Their usual arms were a sabre, a lance, a jereed or dart about two feet long, which they hurled with great dexterity and strength, and a second sabre, or rather broadsword, attached to the saddle. Some of them had also a carabine and one or two pistols. At one time they were the most formidable body of cavalry in the Turkish army; but being an undisciplined and unruly militia, they were, together with the Janizaries, dissolved by sultan Mahmud, and their place is now supplied by the Bashi Bazouks. [JANIZARIES.]

SPANIOLITMIN. [LICHENS, COLOURING MATTERS OF.]

SPARTEIN. [SCOPARIN.]

SPASM (from the Greek σπασμός) is an unhealthy, involuntary, and forcible contraction of muscular tissue. The term is almost synonymous with *convulsion*, but is more generally applied than that word is to the unhealthy painful contractions of the heart, intestines, and other involuntary muscles.

Nosologists have distinguished spasms into clonic, in which the muscular contractions alternate rapidly with relaxations (as in epilepsy), and tonic, in which the contracted fibres remain for a long time rigid, as in tetanus; but in nature the distinction is not well marked. Spasm has also often been regarded as occurring in many tissues in which it is perhaps not possible, such as the small blood-vessels. In the present day its occurrence is believed to be limited to the muscles. What their condition is when affected by spasm is not precisely known. Very generally the contraction is unnatural, not only in its origin and its continuance, but in its extent; for it does not take place simultaneously, or in a regular succession, in each part of the muscle, but, as one may often see in common cramp, it affects a single portion of the muscle, drawing it up into a hard mass, while the fibres above and below it are much less contracted, or are even elongated.

The greater number of spasms seem to depend on an irritation of the nervous centres. Sometimes they are produced by primary disease in those parts, but much more commonly they are the results of irritation propagated from some disordered organ to the brain or spinal cord, and thence reflected through the motor nerves of the muscles in which the spasm occurs. Hence probably the frequency and the aggravation of cramps, and other more important spasmodic affections, when the digestive organs are disordered, the dependence of a variety of spasms or convulsions on the irritation of teething, &c. Much less, however, is known of the nature of spasm in general than of the best methods of treating it, and of the effects which it produces in the several organs which it affects. These are treated of in the articles ANGINA PECTORIS; ANTISPASMODICS; ASTHMA; COLIC; CONVULSIONS; EPILEPSY; HYDROPHOBIA; TETANUS, &c.

SPEAKER. [PARLIAMENT.]

SPEAKING-MACHINE. Various attempts have been made to imitate the human voice by means of a machine. In 1779, the Imperial Academy of St. Petersburg proposed, as one of their prize questions, an inquiry into the nature of the vowel sounds, and the construction of an instrument for imitating them. The prize was awarded to M. Kratzenstein ('Journal de Physique,' xxi), and his principle consisted in the adaptation of a free reed, in all respects similar to that represented under HARMONIUM, to a set of pipes of peculiar forms, determined by repeated trials. About the same time, M. Kempelen, of Vienna, best known for his ingenious fraud, the so-called automaton chess-player, succeeded in producing the vowel sounds by adapting a reed to the bottom of a funnel-shaped cavity, and placing his hand in various positions within the funnel. He also contrived a hollow oval box, divided into two portions, attached by a hinge so as to resemble jaws, and by opening and closing them the sounds which issued from a tube connected with the reed produced A, O, OU, and an imperfect E, but not I. He afterwards succeeded in obtaining, from different jaws, the sound of the consonants P, M, L; and by means of these vowels and consonants he could produce such words as *mamma, papa, aula, lama, mulo.* He afterwards succeeded in imitating the human organs of speech by having only one mouth and one glottis. The mouth consisted of a funnel- or bell-shaped piece of elastic gum, to which was added a nose made of two tin tubes. When both tubes were open, and the mouthpiece closed, a perfect M was produced; and when one was closed and the other open, an N was sounded. He also obtained a tolerable resemblance of the four sounds D, G, K, T, or rather a modified P, and at length succeeded in producing entire words and sentences, such as *Constantinopolis; opera; astronomy; Vous etes mon ami; Je vous aime de tout mon cœur.* We learn from a letter from Mr. Thos. Collinson to Dr. Hutton, who had seen the machine in London, and afterwards at Kempelen's house in Vienna, that the sounds issued, not from a speaking figure, but from a rectangular box about three feet long, placed upon a table and covered with a cloth. Kempelen set it in action by introducing his hands beneath the cloth.

Professor Willis, in the third volume of the 'Transactions of the Cambridge Philosophical Society,' shows that by using a shallower cavity than that employed by Kempelen, he could dispense with the introduction of the hand, and by sliding a flat board over the mouth of the cavity could obtain the whole series of vowels, in the order U, O, A, E, I. The apparatus was, of course, connected with a wind-chest and a double pair of bellows. Mr. Willis also used cylindrical tubes containing a reed, with a contrivance for varying the length of the tubes by means of sliding joints. When the tube was much less than the length of a stop-pipe in unison with the reed it sounded I: and by increasing the length of the tube it gave E, A, O, and U; but what was remarkable, when the tube was lengthened so as to be 1¼ times the length of a stop-pipe in unison with the reed, the vowels began to be sounded in an inverted order,—namely, U, O, A, E,—and then again in a direct order, I, E, A, O, U, when the length of the tube was equal with twice that of a stop-pipe in unison with the reed. When the pitch of the reed was very high, it was impossible to sound some of the vowels, which Mr. Willis remarks is exactly the case with the human voice, female singers being unable to pronounce U and O on the highest notes of their voices.

SPEAKING TRUMPET. The efficiency of this instrument is due to the repeated reflection of the sound from side to side in passing through it, and its ultimate reflection from the mouth of the trumpet, in such a way as either to collect the rays of sound into a focus at a distance, or to project them forward in parallel lines, instead of allowing them to diverge in all directions. *Fig.* 1, illustrates this theory, of which there are many modifications, some of them founded on the supposition of a very close analogy between the motion of sound and that of light. These have given rise to many suggestions respecting the best form and degree of curvature of the sides of the trumpet. Some writers recommend a simple cone, the mouth-piece being at the apex: these explain the motion of the rays of sound on the principle shown in *fig.* 2, in which, as in *fig.* 1, the dotted lines represent the rays.

Fig. 1.

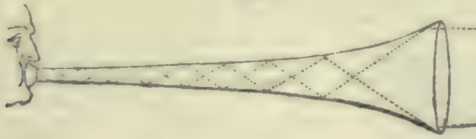


Fig. 2.

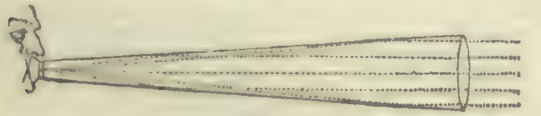


In Dr. Young's 'Lectures on Natural Philosophy,' the following remarks occur: "If an ellipsis be prolonged without limit, it will become a parabola; hence a parabola is the proper form of the section of a tube calculated for collecting a sound which proceeds from a great distance into a single point, or for carrying a sound nearly in parallel directions to a very distant place. It appears, therefore, that a parabolic conoid is the best form for a hearing trumpet, and for a speaking trumpet; but for both purposes the parabola ought to be much elongated, and to consist of a portion of the conoid remote from the vertex; for it is requisite in order to avoid confusion, that the sound should enter the ear in directions confined within certain limits: the voice proceeds also from the mouth without any very considerable divergence, so that the parts of the curve behind the focus would in both cases be wholly useless. A trumpet of such a shape does not very materially differ from a part of a cone, and conical instruments are found to answer sufficiently well for practice; it appears, however, unnecessary to suppose, as M. Lambert has done, that they differ essentially in principle from parabolic trumpets. It is not yet perfectly decided whether or no a speaking trumpet has any immediate effect in strengthening the voice independently of the reflection of sound." [Ear Trumpet.]

Speaking Tubes are used in large buildings for conveying messages from one part to another, and sometimes on shipboard from the captain's cabin to the topmast. These tubes are cylindrical, and the rays of sound proceeding from the mouth at one end of the tube instead of diverging in the air are confined within the tube, and successively reflected from its sides, so that a much larger number of rays meet the ear at the farther end than if they had travelled without being reflected. The shafts of mines, wells, and chimneys produce a similar effect.

SPECIAL OCCUPANCY. [Occupancy.]

SPECIALTY, SPECIALTY DEBT, or debt by special contract, is a debt which becomes due or is acknowledged to be due by an instrument under seal. [Deed.]

The nature of a debt by simple contract is explained under Simlpe Contract.

Blackstone considers a debt of record, that is, a debt which appears to be due by the judgment of a court of record, as a "contract of the highest nature, being established by the sentence of a court of judicature." This is, however, an erroneous view of the matter. It is simply a rule of law that a debt for which the judgment of a court of record has been obtained has a priority over other debts.

SPECIES. This word is used in mathematics, or rather has been used, in two different senses. In the first place, by Euclid, who means by figures of the same species those which have the same form, whatever may be their size. Thus, in the Data, when the form of a figure is given, he designates it as given in species (*τῷ εἴδει δεδομένον*). The word species is here used in its primitive sense of *appearance.*

But the term was again used by Vieta in its logical sense, as opposed to individual, in designating the algebraical notation which he first distinctly proposed. Lawyers were in the habit of describing general cases by using an individual name, as Caius or Julius, to signify any person concerned, which they termed description by species. Vieta borrowed the word to signify the use of letters to stand for numbers, when such letters were used to designate members generally, without reference to any one in particular. The logistics (a common term for the science of calculation) thus introduced he called *specious,* and his first tract on the simple operations of algebra is headed 'De Logisticâ Speciosâ.' Hence, for some time, the language of algebra was called the specious notation.

SPECIFIC ELECTRIC INDUCTION. [Electricity.]

SPECIFIC GRAVITY, or, more properly, *specific weight,* is a term used to express the weight of any gas, liquid, or solid, under some given volume; but the unit of weight and unit of volume are usually such, that for some one particular substance the weight of the unit of volume shall be expressed by the unit of weight, or by 10 times, 100 times, or 1000 times that unit. Thus the numbers expressing the specific gravities of different substances denote the actual weights of those substances under the unit of volume; and hence the ratio between the numbers expressing the specific gravities of any two substances is the same as the ratio between the weights of those substances under any two equal volumes, the density of the atmosphere and also the states of those substances with respect to temperature being the same.

Distilled water is the substance usually employed for the purpose of comparing together the weights of all substances except the gases; and because the volume of any substance varies with its temperature, in determining from experiment the specific gravity of any substance, the weight under a given volume is reduced to that which it would become at one constant temperature. The constant temperature adopted in this country is, in general, that which is expressed by 60° of Fahrenheit's thermometer.

From the experiments of Sir George Shuckburgh Evelyn it was found that at the temperature expressed by 39° Fahr., the height of the column of mercury in the barometer being 29·79 inches, the weight of a cubic foot of distilled water was 999·8066 ounces avoirdupois; and reducing this weight conformably to the table of the densities of water at different temperatures which had been given by Biot, it will be found that at a temperature expressed by 60° Fahr., and when the height of the mercurial column is 30 inches, the weight of the cubic foot of water is 999·54 ounces. But in the Parliamentary regulations, which were made in 1825, a cubic inch of water is stated to weigh 252·456 troy grains, the temperature being 62° Fahr., and the height of the barometrical column, 30 inches; and 7000 troy grains are made equivalent to one pound avoirdupois: hence it follows that a cubic foot of water should weigh 997·136 ounces. Either of these numbers is sufficiently near 1000 to make it very proper that this last should be adopted for the specific gravity of water, since a change in the value of the avoirdupois ounce, which would be scarcely appreciable in the ordinary transactions of commerce, would render the ounce an accurate and convenient unit of weight, while the cubic foot constitutes the unit of volume.

In France, since the employment of the decimal scale of weights and measures has become general, the cubic centimetre (·061028 cubic inches English) is the unit of volume, and the gramme (15·432 grains) is the unit of weight. The gramme having been determined by the weight of a cubic centimetre of distilled water of the temperature at which its density is a maximum (39°·2 Fahr.). Thus the weight of a cubic centimetre of any substance being expressed by any number *n* of grammes, *n* is the specific gravity of that substance.

The numbers expressing the specific weights of substances are also taken to represent their densities. Density, properly speaking, denotes the degree of closeness of the particles of a substance to one another; but this is evidently proportional to the number of particles within a given volume of that substance; and since the weight of a body is only the sum of the actions of gravity upon all its particles, it follows that the densities of two substances under equal volumes will be proportional to their specific gravities. It follows also that if two substances have equal densities or specific gravities, their weights will vary with their volumes; and that the weights of bodies are to one another in a ratio compounded of their specific gravities and volumes.

Previously to describing the methods of finding the specific gravities of substances, it will be proper to explain the construction of the hydrostatical balance, which is the instrument employed for the purpose. The beam of this balance rests, as usual, on the lower circumference of a circular perforation in both sides of the fork which holds it, by a pin which is fixed in it perpendicularly to its length and depth, at a small distance above the common centre of gravity of the beam, scales, and weight. The fork is suspended from the middle of a horizontal bar, and this last is suspended from a spring at the top of the pillar which supports the machine. Care is taken that the two arms of the beam are symmetrical, and that the points from whence the scales are suspended are at equal distances from its centre of gravity. Now let the substance which is to be weighed be put in one of the scale dishes, and the number of grains necessary to keep it in equilibrio be put in the other. If the weight of the substance should be an exact number of grains, that weight is determined, but if not, and it were required to ascertain the weight within one-hundredth part of a grain (for example), the following contrivance may be adopted. Suspend in a vertical position from the lower part of the scale containing the substance to be weighed, a brass wire, whose volume and weight have been previously determined, and let part of the length of this wire enter into water which is contained in a vessel underneath the scale. The scales with this wire thus attached to one of them being previously put in equilibrio when the surface of the water is at a certain mark on the wire, let the substance to be weighed be introduced into the scale above the wire, and let weights be placed in the opposite scale till one grain more would be found too great: then gently raising the whole balance till, by the increase of the weight on the side of the scale containing the substance, in consequence of a greater portion of the wire being out of the water, an equilibrium takes place. The wire being graduated so that 100 divisions correspond to a weight equal to one grain, the number of graduations on it between the surface of the water and the fixed mark before mentioned will enable the experimenter to determine the number of hundredths of a grain by which the weight of the substance in the scale exceeds the number of grains already placed in the opposite scale.

If it be required to weigh a substance in water, or in any other liquid, that substance may be suspended in a vessel containing the liquid by a horse-hair attached below the scale opposite to that from whence the wire before mentioned was suspended; and its weight while immersed in the liquid may be found to the hundredth part of a grain, as in the former case. The reason why horse-hair is employed to suspend the substance in water is, that it has very nearly the same specific gravity as that fluid.

A solid body having greater specific gravity than water being thus weighed both in air and water, may have its specific gravity determined, that of the water being supposed to be known or assumed, by the following proportion:—

> The weight lost by immersion in water (that is, the weight of water equal in volume to the volume of the solid [HYDROSTATICS]),
> Is to the weight of the body in air,
> As the specific gravity of the water is to that of the body.

$$\text{Or, }\left.\begin{array}{c}\text{The weight of}\\ \text{an equal bulk}\\ \text{of water.}\end{array}\right\} : \left\{\begin{array}{c}\text{The specific}\\ \text{gravity of}\\ \text{water}=1{\cdot}000\end{array}\right\} :: \left\{\begin{array}{c}\text{The weight}\\ \text{of the body}\\ \text{in air.}\end{array}\right\} : \left\{\begin{array}{c}\text{The specific}\\ \text{gravity}\\ \text{required.}\end{array}\right.$$

The specific gravity of a fluid is found by weighing any one and the same solid body in air, in water, and also in the fluid, and observing the two differences of weight. These differences are the weights of quantities of the two fluids which are equal in volume to the solid body; and they are to one another as the specific gravities of the two fluids: hence that specific gravity which was required may be found. [See also HYDROSTATICS.] It should be observed that the specific gravity of the solid must be greater than that of either of the fluids, in order that the solid may sink when immersed in them.

The specific gravity of a liquid may be conveniently determined by means of a *specific gravity bottle*, a light bottle containing exactly 1000 grains of distilled water at 60°, so that when the bottle is filled with the liquid whose specific gravity is to be determined, the weight in grains of the liquid immediately determines the specific gravity required. There is usually a counterpoise for the weight of the empty bottle. If such a bottle be counterpoised and then be filled with pure alcohol it will weigh only 792 grains, thus giving 0·792 as the specific gravity of the alcohol. If the bottle were filled with sulphuric acid it would weigh 1845 grains, so that 1·845 would be the specific gravity of the acid. In some cases bottles containing only 100 or 200 grains may be used with advantage.

The density of a powder not soluble in water may be ascertained by means of the specific gravity bottle, or if soluble in water spirits of wine, oil of turpentine, or some other liquid, may be employed. But suppose the powder to be sand, we weigh into the 1000 grain bottle say 150 grains of the sand. If the sand had not displaced any of the water the bottle, when filled up, would weigh 1150 grains; but it is found to weigh only 1096 grains, so that the sand has displaced 54 grains of water. Hence

54 : 1·000 : : 150 : 2·764 = the specific gravity of the sand.

If the body whose specific gravity is to be found be a solid lighter than water, there must be annexed to it, before it is weighed, a mass of some material of known specific gravity, and such that the two bodies may together sink in the water. The compound mass, and the heavier body alone, must be weighed both in air and water; also the lighter body must be weighed in air. Let W be the weight of the compound mass in air, and W′ the weight of the same mass in water; also let *w* be the weight of the heavier body in air, and *w′* the weight of the same body in water: then W—W′ is the weight of water equal in volume to the compound body, and *w*—*w′* is the weight of water equal in volume to the heavier body. The difference between W—W′ and *w*—*w′* is the weight of water equal in volume to the lighter body; therefore, by hydrostatics, that difference is to the specific gravity of water as the weight of the lighter body is to its specific gravity.

When the body is soluble in water, it may be weighed in air, and also in some fluid whose specific gravity is known, and which is not capable of dissolving it; then its specific gravity may be found by the first of the above-mentioned rules, substituting the weight lost in the fluid for the weight lost in water.

If the solid body imbibes water without being dissolved in it, let it be weighed when perfectly dry, and call that weight W: again, we find the weight of water displaced by the body when dry, and call it D; then D is to W as the specific gravity of water is to the specific gravity of the body in its actual state. But D—W is the weight of the water displaced by the solid part only of the body; therefore D—W is to W as the specific gravity of water is to the specific gravity of the solid part only of the body.

It must be observed that the true weight of any body, or that which the body would appear to have if weighed in vacuo, is greater than the weight which it is observed to have when weighed in air, by the weight of a volume of air equal to the difference between the volume of the body and that of the object by which the weight is determined. It should also be observed that the numbers expressing the specific gravities of substances are strictly correct only on the parallel of latitude passing through the place where the weight of the water under the unit of volume is determined; for the force of gravity, and consequently the weight of any substance under a given volume, increases in proceeding from the equator towards either pole of the earth.

In order to determine the specific gravity of the atmosphere, or of any gas whatever, the air or gas must be weighed in a globular vessel of glass, of sufficient magnitude to prevent the unavoidable errors of the operation from sensibly affecting the results.

In taking the specific gravities of gases, correction must be made for temperature. It is known that for every degree of Fahrenheit's scale there is an expansion equal to $\frac{1}{491}$ of the bulk occupied at 32° Fahr. If, for example, 9·2 cubic inches of gas at 70° were reduced to 60° the change in volume would be as follows:—Since 70—32=38, 491 parts of a gas at 32° would at 70° have increased in bulk 38 parts or would have become equal to 529 parts. Again 60—32=28, so that a gas which at 32° occupied 491 parts, would at 60° occupy a space equal to 519 parts. The volume therefore of any gas at 70° would bear the same proportion to the bulk which it would occupy at 60° as 529 does to 519. Hence, 529 : 519 : : 9·2 : 9·026 cubic inches. A correction is also required for pressure; but in taking the specific gravity of a gas, Regnault has reduced the number of corrections required by counterpoising the globe in which the gas is to be weighed by a second globe of equal size. The film of moisture adhering to the glass is equal in both globes, and as the bulk of air displaced is equal in both cases, the calculation for its buoyancy is thus got rid of. A balance capable of weighing 2 lbs., and turning with the 150th part of a grain when loaded, is placed on a chest, furnished with folding doors, within which the glass globes, each of the capacity of about 600 cubic inches, attached to the scale pans, are freely suspended. The counterpoise globe is hermetically sealed, the other globe is furnished with a stop-cock, the air is exhausted from it, and it is filled with the gas to be tried in a pure and dry state. The globe is again exhausted so as to get rid of the last portions of atmospheric air, when it is again filled with the gas, which may be again pumped out and again filled. To get rid of the correction for temperature the globe is placed in melting ice, which reduces the gas to the French standard; more gas is introduced to equalise the pressure, the stop-cock is then closed, the globe withdrawn and wiped carefully with a damp cloth to prevent the surface from becoming electric, and it is then attached to the scale-pan. Two hours are allowed to elapse before it is weighed, in order that it may acquire the temperature of the surrounding air and get rid of the currents about it. The weight is then accurately noted, the globe again plunged in ice, the gas removed by means of the air pump, and the elasticity of the remaining portion in the globe measured by the pump gauge. The empty globe is again weighed as before, and the difference of the two weights will give the weight of a bulk of gas the elasticity of which is equal to that of the atmosphere as marked by the height of the barometer H' diminished by the elasticity h of the remaining gas as measured by the gauge. If the capacity of the globe has been previously determined with accuracy, the corrected weight of the gas will be obtained by the following proportion :—

	The standard pressure.	The observed pressure.	The observed weight.	Corrected weight.
As	H :	$H'-h$: :	W' :	W

The following table has been calculated by Professor Miller from Regnault's experiments, and reduced to the English standard temperature and pressure.

100 Cubic Inches weigh	At 32° Fahr. Grains.	At 60° Fahr. Grains.	Sp. gr. Air=1.
Air	32·698	30·935	1·0000
Oxygen	36·153	34·203	1·1056
Nitrogen	31·762	30·119	0·9713
Hydrogen	2·265	2·143	0·0692
Carbonic acid	50·000	47·303	1·5290

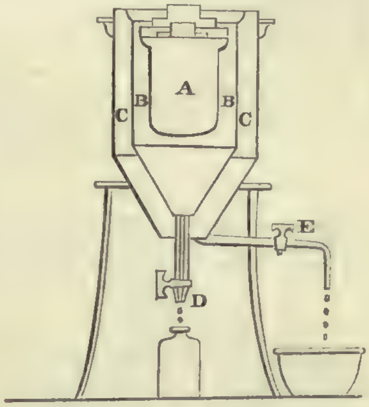
For further details on this subject, and for the method of determining the specific gravity of vapours, we must refer to Professor Miller's 'Elements of Chemistry,' Part I. 2nd edition, 1860. In the appendix to the third part of that work will be found tables of specific gravities corresponding to degrees of Baumé's hydrometer, and also of Twaddell's hydrometer, the latter being converted into their corresponding specific gravities by multiplying them by 5 and adding 1000. The specific gravities of the various solids, liquids and gases are given under their respective heads in this Cyclopædia, also in works on Chemistry. Copious tables are also published in a separate form. As a sample of such tables, a list of the specific gravities of the metals is given at the end of this article. A number of instruments on the principle of the HYDROMETER are sold in the shops, such as the *Areometer*, the *Lactometer* for testing the quality of milk, the *Saccharometer* for enabling the brewer to form an estimate of the quality of his sweet-wort, and some others. The *Barometrical Aëriometer* consists of a tall siphon tube, inverted and mounted on a pedestal with a graduated scale between the two limbs. It was intended to compare the specific gravities of immiscible liquids; thus 1 inch of mercury in one limb will balance about 13½ inches in the other limb. Brewster's *Staktometer* or *Drop-measurer* is an instrument for measuring specific gravities by the size of the drops which exude from a small orifice. The instrument is formed like a pipette, and is filled by the action of the mouth with distilled water, and the number of drops which escape between an upper and a lower level are counted, and serve as a standard. The instrument may now be filled, say with proof spirit, and the drops similarly counted. In one instrument the number of drops of water was 724, while the number with proof spirit was 2117, thus indicating that the drop of water was about three times the size of the drop of proof spirit. What are called *specific gravity beads* or hollow beads of different sizes with projecting tails, and marked with certain numbers, are used to show roughly the density of a liquid. A number of these beads being thrown into it, those which sink or swim are of no account, but those which remain just suspended indicate the specific gravity.

Metals.	Sp. gr.	Metals.	Sp. gr.
Platinum	21·5	Iron	7·844
Osmium	21·4	Tin	7·292
Gold	19·34	Zinc	7·146
Uranium	18·4	Chromium	6·81
Tungsten	17·6	Antimony	6·71
Mercury	13·596	Tellurium	6·25
Palladium	11·8	Arsenic	5·969–5·7
Ruthenium	11·4	Aluminum, rolled	2·67
Lead	11·36	,, cast	2·56
Silver	10·53	Strontium	2·54
Bismuth	9·799	Glucinum	2·1
Cobalt	8·95	Magnesium	1·743
Copper	8·92	Calcium	1·578
Nickel	8·82	Sodium	0·972
Molybdenum	8·62	Potassium	0·865
Cadmium	8·604	Lithium	0·593
Manganese	8·013		

SPECIFIC HEAT. If 1 lb. of water and 1 lb. of oil be transferred from a temperature of 40° to one of 70°, the oil will indicate 70° much quicker than the water, requiring in fact less heat to reach the same temperature. So also if these two bodies be removed from a warm to a cold atmosphere the oil will cool much quicker than the water. In comparing various bodies with water it will be found that they all vary in their rates of heating and cooling. Taking water as the standard of comparison, the thermal unit is the quantity of heat required to raise 1 lb. of pure water from 32° to 33°. And in general the quantity of heat required to raise 1 lb. of any other body from 32° to 33° is called its *specific heat*. When the quantity of heat required to raise the temperature of a body one degree is uniform throughout, or in a very large portion of the thermometric scale, the specific heat of such body is said to be uniform. Where such is not the case, it is said to be variable, and is in general found to increase with the temperature.

Three methods are adopted in *calorimetry*, as it is called, to distinguish it from *thermometry*, or the measuring of sensible or apparent heat. First, by measuring the heat by the quantity of ice which the body in question liquefies; Secondly, by calculating it by the method of mixtures; Thirdly, by observing the rate at which heated bodies cool.

By the first method the calorimeter of Messrs. Lavoisier and Laplace is used. It consists of two similar metallic vessels, one smaller than and contained in the other, so as to leave a space C C. From this space proceeds a discharge-pipe with a stop-cock E. From the bottom of the inner vessel also proceeds a pipe D; it passes air-tight through the outer vessel, and is furnished with a stop-cock. There is a third vessel, A, contained within the second, and the space B B is also filled with pounded ice. The vessel A is furnished with a cover, and there is a large tray-like cover over the whole apparatus. This is also filled with pounded ice. Now supposing such an apparatus to be introduced into a room at a temperature of 40°, it is evident that the ice in C will slowly melt, and retain B at the constant temperature of 32°. Now if we introduce the body whose specific heat is to be determined into A at any given temperature above 32°, it would cool down to that temperature, and in doing so will melt a quantity of ice, the water from which will be collected in the bottle below D. If this quantity of water be divided by the number of degrees through which the body in A has fallen, the quantity of ice dissolved by the heat corresponding to 1° will be found. This being divided by the weight of the body in A in pounds, the weight of ice dissolved by the heat which would raise 1 lb. of the body 1° will be determined. In this way it is found that the heat necessary to raise 1 lb. of water 1°, is that which would dissolve the 142·65th part of 1 lb. of ice. For other bodies we get the following rule :—Multiply the weight of ice dissolved by 142·65, and multiply the weight of the body which dissolves the ice, by the number of degrees of temperature which it loses, and divide the former product by the latter, when the quotient will be the specific heat of the body.



By the method of mixtures a mean temperature is obtained, when equal weights of the same body are mingled together; but when different fluids are mixed the result is different. For example, 1 lb. of mercury at 40° agitated with 1 lb. of water at 156°, gives a mixture =152°·3. In this case the water loses 3°·7, and the mercury gains 112°·3. Hence 112°·3 : 3°·7 : : 1 : 0·033, or, in other words, water being 1000, the specific heat of mercury is only 33; 1 lb. of water absorbing 30 times more heat than 1 lb. of mercury.

By the third method equal and similar volumes of two bodies are raised to the same temperature, and allowed to cool under similar circumstances. By observing the intervals of time required for equal volumes to fall 1°, we get the ratio of the quantities of heat which they lose. The quantities for equal weights may be inferred from the specific gravities of the bodies, and in this way the specific heats can be arrived at.

The specific heat of bodies diminishes with an increase of density, so that mere mechanical compression will raise the temperature of many bodies, and even make some of the metals very hot; iron, it is said, incandescent. The sudden compression of aëriform bodies is attended with the evolution of heat, sufficient under proper arrangements to ignite *amadou*, or German tinder. On rarefying air an opposite effect is observed, as is evident from the dimness seen on the inner surface of an air-pump receiver on first beginning to exhaust the air. The capacity for heat of the remaining air is increased, and there is not sufficient heat to retain the vapour in its elastic form. So when compressed air suddenly escapes, it absorbs heat, and moisture is deposited. Similar effects may be observed in nature. A blast of cold air descending from a lofty height, has its temperature raised by the mere compression that it undergoes.

The following are a few specific heats obtained by the process of mixture or immersion. They refer to that part of the scale between 32° and 212°:—

Water	1·00000	Brass	0·09391
Oil of turpentine	0·42593	Silver	0·05701
Charcoal	0·24150	Tin	0·05623
Glass	0·19768	Mercury	0·03332
Iron	0·11379	Platinum	0·03243
Zinc	0·09555	Gold	0·03244
Copper	0·09515	Lead	0·03140

A body in the liquid state has a higher specific heat than the same substance in a solid form. The specific heat of water, for example, is double that of ice. Indeed the large specific heat of water has a great effect on the temperature of the globe, in moderating the rapidity of the transitions which would otherwise occur.

The determination of the specific heats of gases and vapours is attended with difficulty. Regnault's results are probably very near the truth. Taking the specific heat of an equal weight of water as the unit of comparison, he finds that of air to be = 0·2377. The following are a few of his results:—

Gas or Vapour.	Equal vols.	Equal weights.	Gas or Vapour.	Equal vols.	Equal weights.
Oxygen	0·2412	0·2182	Carbonic acid	0·3308	0·2164
Nitrogen	0·2370	0·2440	Ammonia	0·2994	0·5080
Hydrogen	0·2356	3·4046	Olefiant gas	0·3572	0·3694
Chlorine	0·2962	0·1214	Sulphurous acid	0·3489	0·1553
Bromine	0·2992	0·0552	Water	0·2950	0·4750
Nitrous oxide	0·3413	0·2238	Alcohol	0·7171	0·4513
Nitric oxide	0·2406	0·2315	Ether	1·2296	0·4810
Carbonic oxide	0·2399	0·2479	Oil of turpentine	2·3776	0·5061

There is a remarkable relation between the specific heat of an elementary body and its chemical equivalent. If the specific heat of a body in the solid state be multiplied into the chemical equivalent of the same body, it gives a number which coincides almost exactly with the product obtained by multiplying together the specific heat and the equivalent of any other elementary substance.

SPECIFICATION. [PATENT.]

SPECTACLES are lenses so mounted in frames as to be conveniently held before the eyes to assist defective vision. The eyes of a person whose sight is much tried often receive injury from delay in the use of spectacles; while the sight of many persons is prematurely worn out by the use of glasses of too high a power. Whether the glasses used be concave or convex, the lowest power that is available should be used. The use of a single reading-glass instead of spectacles is injurious, since, by occasioning one eye to be more used than the other, the power and focal length of the two are rendered unequal. The unsteadiness of the glass is also a disadvantage. The defects of the single hand glass are not removed by increasing its size so much that both eyes may see through it, because in that case the axis of each pencil of rays will be distorted by passing through the lens at points beside its centre. Hand-spectacles, which are made to fold up into nearly as small a space as a single glass, are better than reading-glasses; but, although steadied in some degree by resting upon the nose, they are not equal to spectacles well fitted to and supported by the head.

Varieties in the conformation of the eyes, and in the manner and degree in which they are affected by use, render it impossible to lay down any rule for the focal length of convex glasses for persons of a given age; yet a general idea of the necessary power may be obtained from the following table, extracted from Dr. Kitchener's 'Economy of the Eyes:'—

Years of age.	Inches of focus.	Years of age.	Inches of focus.
40	36	70	12
45	30	75	10
50	24	80	9
55	20	85	8
58	18	90	7
60	16	100	6
65	14		

In some cases it is advisable to use different spectacles for night and day, to suit different degrees of light; and it is, generally speaking, well to increase the power of the glasses as the sight becomes weaker from age. Even in this, however, caution must be exercised, lest, by over-stimulating the eye, its powers be too rapidly exhausted. It should always be borne in mind, both by young and old persons, and in changing spectacles as well as in first taking to them, that the ultimate object of convex spectacles is to restore the natural power (or rather the natural *focus*) of the eye, and not to enable the wearer to see objects larger or more distinctly than with the eye in a strong and healthy condition. Short-sightedness being still less dependent upon age, cannot be met by any rule even so well as the opposite defect.

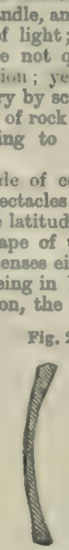
In choosing spectacles, the frame should fit comfortably to the head, and be of such a form as to bring the centre of each lens exactly opposite to the centre of the eye. Should this not be the case, the bridge or wire that unites the two halves of the frame may be stretched or bent to suit the wearer.

With respect to the glass used in spectacles, it may be taken as a rule that, except in cases where it is necessary to protect the eyes from an injurious glare of light, the most colourless material is to be preferred. The accurate figure of the lenses cannot be too strongly insisted on, and may be tested by holding the spectacles near to a printed book, and gradually moving them nearer to the eye; by doing which, if the glasses be not well-shaped, the letters will appear distorted. Veins or blebs in the glass are injurious, and may be detected by holding the glass between the eye and the flame of a candle, and moving it backwards and forwards, until it appears full of light; when every such defect will be distinctly seen. Scratches are not quite so injurious, inasmuch as they do not produce distortion; yet they should be avoided. Their diminished liability to injury by scratching forms the principal recommendation of spectacle lenses of rock crystal; but some opticians consider their use injurious, owing to their tendency to irregular refraction of the rays of light.

Several deviations from the ordinary mode of constructing spectacles may be alluded to. The *periscopic* spectacles of Dr. Wollaston were contrived in order to allow considerable latitude of motion to the eyes without fatigue, by conforming the shape of the glasses to that of the eyes. This is effected by the use of lenses either of a meniscus or concavo-convex form: the concave side being in both cases turned towards the eye. *Fig.* 1 represents in section, the form of the lens used in convex or magnifying spectacles of the periscopic construction; and *Fig.* 2 shows that of a concave lens suitable for short-sighted persons. In the former case the curve of least radius is that of the anterior, and in the latter, that of the posterior surface of the lens.

Fig. 1.

Fig. 2.



Divided spectacles, each glass consisting of two half-lenses, are sometimes used; the upper half of each glass being occupied by a concave lens, or one of very slight convexity, for seeing distant objects, while the lower half has a strong magnifier, for examining things near the eye. Such spectacles have an awkward appearance, on account of the joint along the middle, and require some practice to avoid inconvenience to the wearer; but they have been used with advantage by artists and others requiring to look alternately at near and distant objects. Other plans have been tried for obtaining a similar advantage; such as having a second pair of glasses hinged to the frame, and capable of either turning up out of the way, or being placed immediately before the ordinary lenses, to modify their power; or having two distinct pairs of spectacles, capable of being used either separately or together. Spectacles with glazed wings, or frames partly filled with crape, are sometimes used by travellers; the glasses, which may be plain, unless otherwise required, being of such a form as to shield the eyes from dust.

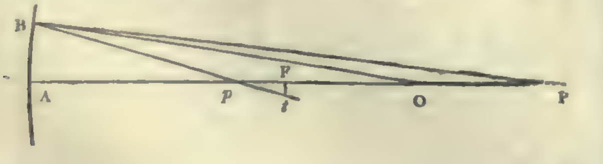
In the Great Exhibition of 1851 the British exhibitors of spectacles were contented with improvements in the method of mounting, but left out of sight the main object, the improvement of the glasses. Thus there were fine and delicate frames, some weighing only 11 grains, and the whole weight, including glasses, not amounting to more than two pennyweights. The steel frames of these spectacles resembled hair lines, and were imperceptible at a short distance. There were also ventilating eye-shades, designed to allow a current of air to circulate freely between the shade and the wearer: there were also spectacles for sketching, mounted without a rim to prevent obstruction of vision. These, with every variety of gold, silver, and steel-mounted spectacles, were to be found in abundance; but it was left to the French exhibitors to present glasses to suit almost every peculiarity of vision. M. Henri, uniting the skill of the optician with the knowledge of the physiologist, exhibited spectacles of an improved kind, the glass of which was so pure as to remove one source of uneasiness and fatigue incident upon the use of spectacles; while the foci were so arranged as to rectify certain defects and obliquity of vision. Some of these spectacles were furnished with a moveable diaphragm, to be shifted right or left at will. These were designed for the cure of squinting, either converging or diverging. M. Pouillot exhibited metallic woven spectacles for the free admission of air to the eyes, while they serve as a screen against dust, insects, &c., and also subdue the light.

SPECTRUM (in optics) is the name applied to the coloured image of the sun, or a narrow luminous object, when the light proceeding from it is transmitted through a prism, and either allowed to fall on a screen at some distance, or received directly into the eye. [Dispersion.] A similar coloured image, produced by diffraction, may be obtained without a prism [Diffraction of Light], and to it the term *spectrum* equally applies.

The fixed lines of the solar spectrum have been already mentioned in the former of the articles just quoted. Much light has recently been thrown on their origin by the labours of Professor Kirchoff. Fraunhofer long ago observed that the spectrum of a candle, or of a spirit-lamp, exhibits a double *bright* line, which *exactly coincides in position* with the double *dark* line D of the solar spectrum; and Sir David Brewster noticed a similar correspondence in the case of deflagrating nitre. ('Report of the British Association,' for 1842, p. 15.) An imitation of the fixed lines of the solar spectrum, as to their general character, is obtained by subjecting light to the absorbing action of certain gases, as was first discovered by Sir David Brewster, in the case of nitrous acid gas. If the light of a lamp, which, if unmodified, would give a continuous spectrum, be transmitted through this gas, and then analysed, the spectrum is seen to be traversed by numerous dark lines or narrow bands, which by their sharpness of definition, narrowness, and apparently capricious arrangement, remind one of the lines of the solar spectrum. That *some* of the fixed lines of the spectrum seen when the sun is near the horizon are to be attributed to absorption by the earth's atmosphere, is evident from the fact that they are not seen when the sun is high; but that *all* have not this origin seems to follow from the fact, observed by Fraunhofer, that different fixed stars have lines of their own, whereas were all the lines due to absorption in the earth's atmosphere, the same system ought to be seen whether the source of light were the sun or a fixed star.

During the researches in which he was engaged, in common with Professor Bunsen, on the application of the prismatic analysis of flames to qualitative chemical analysis, Professor Kirchoff was led to discover that flames which exhibit in their spectra bright lines of certain definite refrangibilities at the same time absorb energetically light of those precise degrees of refrangibility. (Poggendorff's 'Annalen,' vol. cx., p. 161; or 'Phil. Mag.' for August, 1860.) He further connected this phenomenon with Prevost's theory of exchanges. He found that if behind a flame giving bright lines in its spectrum were placed a brilliantly luminous body of higher temperature, giving itself alone a continuous spectrum, the compound light, consisting partly of light emitted by the flame, partly of light emitted by the luminous body behind it and transmitted through the flame, exhibited on analysis dark lines in the places of the bright lines given by the flame alone; the regions of those lines, as compared with the neighbouring regions, suffering more in luminosity by absorption of the light from the luminous body than they gained by the light emitted by the flame. A particular instance of this simultaneous emission and absorption of rays of definite refrangibility had been observed in the case of the voltaic arc many years before by Foucault ('L'Institut,' for Feb. 7, 1849), who, however, had not further followed the observation, nor connected it with the theory of exchanges. Now the outer portions of the atmosphere of the sun or a star, and the inner portions, or else the solid or liquid body itself, may be conceived to be in the same relative condition as the flame in the above experiment and the luminous body behind it; and thus we are led to connect the *dark* lines seen in the spectra of light coming directly from the sun or a fixed star, with the presence in their atmospheres, in a state of incandescence, of those elements, which, when present in flames, cause them to give out *bright* lines of the same refrangibility. It is found that the introduction of small quantities of various metallic salts into a flame causes its spectrum to exhibit bright lines, depending upon, and characteristic of, the metal introduced; and by comparing these lines with the dark lines of the solar spectrum we may infer the presence or absence of such metals therein. Thus Professors Bunsen and Kirchoff have concluded that the solar atmosphere contains potassium and sodium, that lithium is absent, or present in comparatively small quantity, and so forth.

SPE'CULUM, a name frequently given to a mirror used for any scientific purpose, as in a reflecting telescope. For the astronomical bearings of the speculum we refer to Telescope, but we here give the first part of the simpler mathematical description of a pencil of rays incident upon a mirror, so as to make this article a counterpart to Lens.



The convex mirror is comparatively of no importance, and the formulæ for it may be easily derived from those for the concave mirror, to which we proceed, referring to Mr. Griffin's work on Optics for further information. Let a pencil of rays fall on the spherical mirror A B from the point P, of which rays P B is one. Let P B be reflected into B p. It is supposed that P is in the radius O A, which is the axis of the mirror; O being the centre of the sphere. Let $AO=r$, $AP=u$, $Ap=v$. The nearer B is taken to A, the more nearly does the point p approach to a certain point F, at which the image of P is said to be formed: not that any rays are actually reflected to F, but because all the rays which are reflected from points near to A fall exceedingly near to F, which is the cusp, and brightest point of the Caustic. If $AF=w$, the position of F is determined by the equation—

$$\frac{1}{w} = \frac{2}{r} - \frac{1}{u} \ldots. (1)$$

The point p however is always nearer to A, or lies between F and A, and p F, or the longitudinal aberration, is thus found: let the length of the arc A B be y; then

$$p\,F = \frac{w^2}{r}\left(\frac{1}{r} - \frac{1}{u}\right)^2 y^2 \ldots. (2)$$

very nearly, if y be not very great. And for the lateral aberration F t, we have

$$F\,t = \frac{w}{r}\left(\frac{1}{r} - \frac{1}{u}\right)^2 y^3 \ldots. (3).$$

Again, there is for all the rays proceeding from P, after reflection, a circle through which they all pass, as in Lens. The distance of this circle of least aberration from the focus F toward A, is the following expression:—

$$\frac{3}{4}\frac{w^2Y^2}{r}\left(\frac{1}{r} - \frac{1}{u}\right)^2 \ldots. (4).$$

if Y be the whole semi-arc of the mirror: it is therefore three-fourths of the longitudinal aberration of the extreme ray. The diameter of this circle of least aberration is

$$\frac{1}{2}\frac{wY^3}{r}\left(\frac{1}{r} - \frac{1}{u}\right)^2 \ldots. (5),$$

or one-half the lateral aberration of the extreme ray.

When the rays fall parallel to each other on the mirror, u is infinite, and we have $\frac{1}{2}r$ for the value of w, $\frac{y^2}{4r}$ for the longitudinal aberration, $\frac{y^3}{2r^2}$ for the lateral aberration, $\frac{3Y^2}{16r}$ for the distance of the circle of least aberration from the focus, and $\frac{Y^3}{4r}$ for its diameter.

When $u=r$, or the incident pencil is thrown from the centre, it is returned again to the centre, and there are no aberrations.

When u is less than r, or P is between O and A, F then falls beyond O, and, as P approaches to the middle point of O A, recedes without limit. When $u=\frac{1}{2}r$, or P is at the middle point of O A, all the reflected rays are parallel to one another and to the axis of the mirror. And when u is less than $\frac{1}{2}r$, w becomes negative, or the focus is on the other side of the mirror, and the reflected rays diverge; but only the latitudinal aberration alters its sign.

The formulæ for a convex mirror may be found by making r negative in those for a concave mirror. Hence w is always negative, or the focus of every pencil is behind the mirror: the longitudinal aberrations change sign, but not the latitudinal ones: and as w has also changed sign, the effect is that p is always nearer to the mirror than F, as before.

The image in a convex mirror is always upright; and in a concave one always inverted, except when the object falls between the principal focus (or middle point of the radius) and the mirror.

The astronomical value of the speculum depends on the quantity of light that it can concentrate, and on the precision with which it forms the optical image of a distant object. Hence the magnitude, the curvature, and the surface polish are all of importance. The figure may be parabolic, where every part has the same focus, or it may be an ellipsoid, where the edge is of shorter focus than the centre, or if longer an hyperboloid. The grinding and polishing of lenses in a refracting telescope, to say nothing of the difficulty of obtaining good optical glass, greatly limit the perfection of that form of telescope; but an amount of error that would be tolerated in the best lenses, would be fatal in the speculum of a large reflecting telescope. The difficulties of forming an accurate speculum constitute a problem of the highest order, the solution of which has received the careful study of first-rate astronomers and mechanicians. The reader who is desirous of seeing how these difficulties have been overcome, will do well to consult the memoir communicated to the Royal Society of London in 1840 by Lord Oxmantown (now Earl of Rosse) entitled 'An Account of Experiments on the Reflecting Telescope.' We may also refer for a multitude of minute details to Holtzapffel's 'Mechanical Manipulation,' to papers in the proceedings of the British Association, 1843, 1850, to the 'Transactions of the Royal Astronomical Society,' to the 'Philosophical Transactions' for 1850, and also to the article Speculum in Nichol's 'Cyclopædia of the Physical Sciences,' 1860. All we can do, in this place, is to indicate the nature of the problem to be solved, and briefly to state some of the means adopted for its solution.

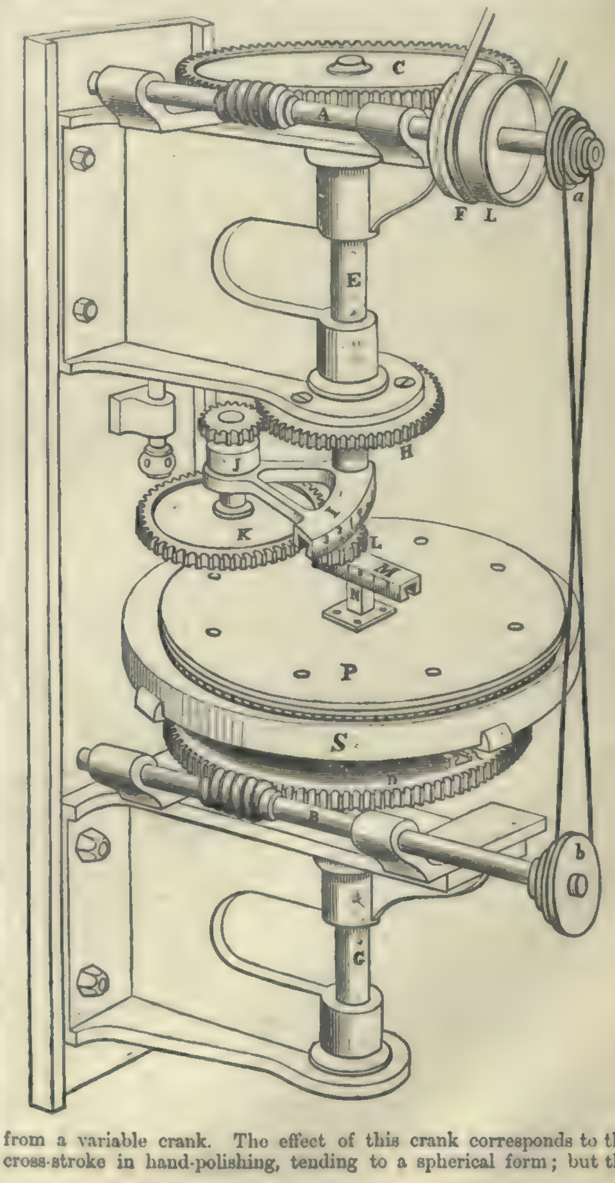
And first as to the material. Speculum metal is an alloy of tin and copper, which according to Lord Rosse should be a definite atomic compound, namely, four equivalents of copper to one of tin, or 126·4 parts of copper to 58·9 of tin, or 32 to 15 nearly. This is the alloy used by Newton in the first reflecting telescope. It is very brilliant, but so brittle as to break with a slight blow or sudden change of temperature, and so hard and friable that it cannot be worked with steel tools. The introduction of other metals or a larger proportion of copper may diminish the brittleness, but will lower the brilliancy, and produce a metal more liable to tarnish. It is remarkable that speculum metal displays its porosity with the aid of a simple Coddington's microscope. [BRONZE; SPECULUM METAL.]

When it is stated that the 6 feet speculum of Lord Rosse's telescope weighs 4 tons, it may be imagined that the casting of such a mass is a work of some difficulty. If a close mould were used, or if the metal were rapidly cooled, it would fly to pieces in attempting to work it, or if cast in sand, as an open casting, it would probably have a spongy or crystalline texture, which would be visible when polished. Small specula are cast in sand, and as soon as they are set the sand core is pushed out of the central aperture of such as are intended for Gregorians, and the red-hot disc is surrounded by ignited wood ashes to delay the cooling; but in large specula the margins solidify first and from want of ductility the central parts are torn away in the act of contracting, and the mass becomes rent or flawed. To prevent these defects and accidents, the speculum is cast on a *chill* or surface of iron moderately heated, the effect of which is to give a fine grain and increased compactness to the metal to a small distance from the surface. In Mr. Lassell's mode a cast-iron mould a little deeper than the speculum, with its bottom convex, and of the same radius, is attached to the end of a strong weighted lever, so that when the mould is empty, its bottom makes a considerable angle with the horizon, but becomes horizontal when charged with the proper quantity of speculum metal. The fused metal is poured into a lateral cell, communicating with the mould at its lowest point. In this way the metal rises smoothly and evenly along the bottom, and entangled air and scoria are got rid of. In Lord Rosse's arrangement the bottom of the mould is made of pieces of hoop iron on edge, wedged tightly in an iron frame, and turned to the proper curvature. This holds the fused metal, but allows the gaseous matter to pass freely through. On this a wooden pattern is laid about twice as deep as the intended speculum and 1-65th larger to allow for contraction: sand is rammed round this, and when the pattern is removed and the metal poured into the cavity, the lower surface is chilled, the sides in contact with the sand next harden, while the central parts remain longer fluid, and the top or back of the speculum congeals last, by which arrangement the contraction and irregularity of texture occur where they are least injurious. While the cast is still red-hot, in which state it is not brittle, it is transferred to an annealing furnace, which has been kept heated for some days so that its interior brickwork is at a full red, and here it is left to cool for a month or six weeks in case of a 6-feet speculum; smaller ones, of course, requiring less time.

The grinding and the polishing, so as to produce a brilliant polish and a true parabolic figure, are still more difficult than the casting. The grinding is done by means of a tool on which are cemented small pieces of gritstone, dressed to the convexity of the surface by means of a gauge of sheet-iron. A convex and a concave gauge should be at hand: circular arcs are struck on them of a radius equal to twice the focal length, and afterwards left free by filing and grinding. When an even surface is produced by this tool, another is taken, of cast-iron, turned to the convex gauge, and cut up into small squares by two sets of grooves, about a quarter of an inch wide. This is charged first with sand, then with emery and water, and is made to traverse the face of the speculum by machinery. There must be occasional washing, and emery of increasing fineness used, till all scratches are removed. The face may be tested optically from time to time, and examined as to the focus. Early in the process the edge of the speculum is ground true with sand applied by means of a divided hoop of iron, which admits of being tightened. The back may also be made uniform. In the grinding, care was taken to prevent the slightest jar of the grinder on the speculum, as the metal is so brittle that there is great danger of breaking it. A number of thin wooden wedges may be placed on the margin of the speculum, and the polisher slowly lowered upon them, and then by degrees they can be gently withdrawn.

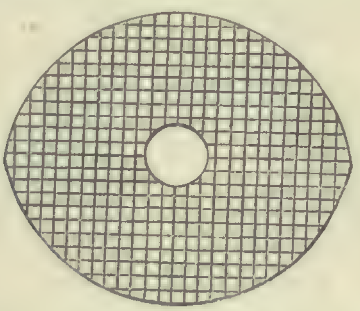
In the polishing process, the tool, sometimes of lighter material than the grinder, is coated with pitch to a small thickness, but not closing the grooves which divide the surface into squares. The pitch must be of the degree of hardness such that a sovereign will stand on it on edge for one minute, and leave the impression of four nicks of the milling. The speculum is cleaned from emery or dust, and properly secured on the polishing-machine, and is smeared with a mixture of water and rouge (peroxide of iron), and the polisher, at the temperature of 80°, is placed on it for a short time. On raising it, all the squares of the pitch must have been in full contact with the speculum. If this be the case, the polisher is ready for work. In the old method of polishing by hand, the polisher is fixed to a firm block, and the operator, holding the speculum by a handle cemented to its back, works it backwards and forwards across the polisher by straight strokes, after a few of which he shifts his position to give them a new direction, turning the speculum somewhat to get rid as far as may be of inequalities in the abrasion; and from time to time these cross-strokes are varied by circular ones; and as the moisture evaporates, a little water must be supplied at the edge. The adhesion and friction increase rapidly; the polishing-powder changes in colour, and at last disappears, when a fine polish covers the speculum, and the operator, by a few circular strokes, completes the parabolic figure.

This may be tested by optical means. Care must be taken not to pass the proper figure, for it cannot be recovered except by re-grinding and repeating the whole process. The advocates for this laborious kind of work attach much importance to the touch of the operator, since he can *feel* if anything is going wrong, and correct it in time. But as hand-polishing cannot be applied to specula above nine inches, and science required those of larger size, the introduction of machinery was necessary to progress. The two Herschels availed themselves of mechanical aid; but the first astronomer who has given a minute account of his method is Lord Rosse, in the paper above referred to. His plan is to work by a double system of cross-strokes, while the speculum and polisher are slowly revolving with unequal velocities. The speculum is carried by a chuck attached to a strong vertical shaft, and is surrounded by water at 55° to insure the proper consistence of the pitch. The polisher is of iron, stiffened by means of ribs arranged like the walls of a honeycomb, and suspended by six points to lessen the chance of bending. The polishing-bar has a rectilinear motion from a variable crank. The effect of this crank corresponds to the cross-stroke in hand-polishing, tending to a spherical form; but the

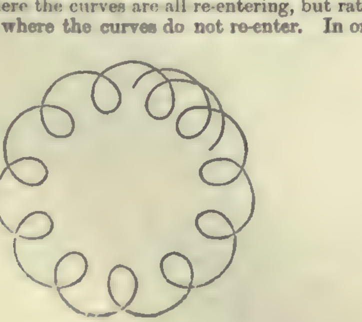


rotation of the speculum tends to lengthen the focus of the exterior zones of its surface. There is also an excentric motion, which augments to any required extent the circumferential action. The figure depends on four things, namely, the radius of the primary, that of the excentric, and the angular velocities of it and the speculum. In polishing a six-feet speculum, the number of strokes is eight per minute; and for smaller ones, inversely as their diameter. The polishing of a six-feet speculum requires five hours. The figure of the speculum was tested in Lord Rosse's process, during the grinding and polishing, by observing the reflection of a watch-dial placed perpendicularly over the speculum, at a height of about 90 feet. By carefully watching the image of this dial, the adjustment of the length of stroke could be made with such accuracy that the three-feet speculum, with its whole aperture, was thrown perceptibly out of focus by a motion of the eye-piece amounting to less than the thirtieth of an inch. During the polishing, it was found necessary, in order to prevent irregular expansion of the speculum, to maintain a uniform temperature in the polishing-room; and it was also necessary to have a certain degree of moisture in the air, that the wet polishing-powder should dry at the proper rate. When the air was too damp, the polishing was not attempted; if it were too dry, a jet of steam was introduced. Instead of water, ammonia soap (or common soap treated with ammonia) was sometimes used with the polishing-powder, as this was found to dry more rapidly.

A more complete idea of the arrangements for grinding and polishing specula may be formed from Mr. Lassell's arrangement, as improved by Mr. Nasmyth, and represented in the figure (col. 704), the object being to imitate as closely as possible those evolutions of the hand by which Mr. Lassell had been accustomed to produce perfect surfaces on smaller specula. F L represent fast and loose pulleys for conveying the power, and transmitting it by the endless screw on the shaft, A, to the wheel C. The spindle, E, of this wheel has attached to it a crank or arm, I, which carries a pinion, J, and causes the pinion to revolve round the toothed circumference of the wheel H, which wheel H, being fixed to a bracket, causes the pinion J to revolve with as many turns as its circumference is less than that of the wheel H, or five to one. The spindle of the pinion J has a wheel, K, fixed to it at its lower end, which wheel K, in like manner, conveys motion to the pinion L, which works on an adjustable centre-pin; and as the T-groove in which the centre-pin of L works is radial to the centre of the wheel H, this pinion may be set to any degree of excentricity, and yet be in gear with H. The pinion L has also a cross-crank, M, attached to its under side, which, having its crank-pin, N, also sliding in a T-groove, it may be set to and fixed at any degree of excentricity; so that by these two excentric movements we have the means of giving to the pin N any compound motion required. The polisher is of wood or other suitable material, coated with pitch, and divided into squares.



This polisher is free to move upon the pin N, while N causes the polisher to slide over the surface of the speculum S with a motion not like that represented in the figure contained in Holtzapffel's 'Mechanical Manipulation,' where the curves are all re-entering, but rather as in the following figure, where the curves do not re-enter. In order that



every part of the surface of the speculum may continually change its position, with respect to the movements of the polisher, a slow revolving motion is given to it by an endless screw on B working into the teeth of the wheel D, which forms the base on which the speculum rests. It rests, in fact, on nine equilibrium points in the cell in which it is to rest when actually in the telescope, so as to incur no risk of distortion. "By means of this arrangement," says Mr. Nasmyth, "a speculum having a decidedly hyperbolic figure may be corrected, and brought to a perfect parabola, or to a spherical curve, or the same may be done in the reverse order, at pleasure." In Lord Rosse's arrangement, the polisher is traversed over the speculum with reciprocating longitudinal motion; and in Mr. Lassell's, the polisher has a continuous epitrochoidal motion, the path of which is dependent upon the adjustments of L and M. The polisher is made of two thicknesses of pine-wood, with the grain crossed. This, from its lightness, does not require to be counterpoised, as in Rosse's; and, apparently from its being sufficiently yielding to accommodate itself somewhat to the form of the speculum, a single coating of pitch was found sufficient, and the polishing was completed with wet powder. The value of the two-feet speculum thus produced is shown by Mr. Lassell's discovery of the satellite of Neptune, an eighth satellite of Saturn, and the re-observation of the satellites of Uranus, which had not been seen since their announcement by Sir W. Herschel. Mr. Lassell's polisher has served as a type to other skilful mechanicians, such as Mr. De la Rue, Mr. Grubb, of Dublin, and Mr. Lassell himself has introduced some modifications.

Further details respecting specula belong to TELESCOPE; but we may mention the proposal, if not introduction, of silver as a substitute for speculum metal. It reflects 0·91 of the incident light, while speculum metal only reflects 0·67. It is, on the other hand, liable to tarnish, and there are difficulties in the way of figuring and polishing it. M. Foucault, however, has formed a speculum of glass, figured and polished to a true parabola, and deposited a thin but uniform film of silver on its surface, by means of Drayton's process, in which a solution of nitrate of silver is reduced by means of oil of cassia. The exterior surface of the glass speculum is parabolic, but has no lustre. That property may be imparted to it in a high degree without any sensible change of figure, by means of light friction with wash-leather and a little peroxide of iron. In case of tarnish, the polish may be renewed by the same process, and often be repeated before the silvering requires to be renewed.

SPECULUM METAL. [BRONZE.]

SPEISS. [COBALT.]

SPELTER. [ZINC.]

SPERMACETI, or CETACEUM, a fatty material, obtained from the *Physeter macrocephalus*, (*Catodons macrocephalus* of Beale) [CETACEA, in NAT. HIST. DIV.], a species of whale, generally met with in the South Seas, but also on the coast of Greenland, and occasionally stranded on the coasts of Britain. When purified it is called *cetine*. It is also soluble in ether, and volatile and fixed oils. It has a white, pearly, or silky appearance, considerable tenacity, but may be broken into mica-like scales, with a smooth or fatty feel, slight fish-like odour, and mild mawkish taste. Its specific gravity is ·943; it melts at 112°, and when a lighted body is applied to it, it burns with a clear flame.

Sulphuric is the only acid which dissolves it. It is only partially dissolved by the fixed alkalies, and is with difficulty saponifiable. Hot caustic ammonia forms with it an emulsion, which is not decomposed on cooling.

Long exposure to the air renders it rancid; it may be again purified by washing in a warm ley of potass. It should be protected from air and light.

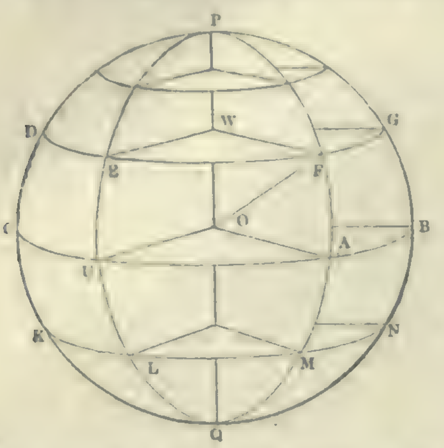
A hundred parts of spermaceti consist of sixty parts of margaric and oleic acids, forty parts of ethal, and 0·9 parts of a yellow extractiform substance. The ultimate composition of cetine seems to be—carbon, 81; hydrogen, 12; oxygen, 5.

Spermaceti possesses the properties common to fatty matters. It is bland and demulcent, with considerable nutritive qualities, when taken internally. It was formerly much used in colds and coughs, united with mucilage or syrup, to shield the throat from the irritation of the air, also in dysentery. Triturated with sugar-candy, and having warm milk added to it, it is a mild nutrient article, fit for children or old persons. It is however now chiefly employed externally as an ingredient in ointments and cerates. It is also largely used to form candles, and to burn in lamps.

SPHERE, or GLOBE, a solid body, the surface of which is everywhere equally distant from a given point or centre within it. This distance of each point from the centre is called the radius. In the article MENSURATION will be found the formulæ which connect the surface and solidity of a sphere with the radius: we shall here add that the weight of a sphere of pure water is found in ounces avoirdupois, by multiplying the cube of the number of inches in the radius by 2·4171; and in pounds avoirdupois by multiplying the cube of the number of feet in the radius by 261·05. These results multiplied by the specific gravity give the weight of a sphere of any other substance.

A section made by a sphere and plane is always a circle. When the cutting plane passes through the centre of the sphere, this proposition is obvious from the definition of a circle. When the plane does not pass through the centre the assertion follows so soon as it is shown that a plane curve having all its points equidistant from a given point *not in the plane* is a circle. A section passing through the centre is called a *great* circle, and one which does not pass through the centre a *small* circle. These terms are incorrect, since a small circle may be in size as nearly as we please equal to a great circle: the words *greater* and *smaller* would be more correct.

The centre of a circular section is found by drawing a perpendicular from the centre of the sphere to the plane of the section. All sections whose planes are parallel have their centres on one straight line, namely, the perpendicular to the planes which passes through the centre of the sphere. The great circle in such a system (C U A B) is called the *primitive*, the common perpendicular (P O Q) the *axis*, all the small circles (D E F G, K L M N, &c.) *parallels*, the extremities of the axis



(P and Q) *poles*, and all great circles passing through the axis and poles (P C Q B, P U Q, P A Q, &c.) *secondaries.*

By the angle made by two great circles is always understood the angle made by their planes, which is also that made by their tangents at the point of intersection, and that made by the intersections of the two circles with the third circle to which both are secondary. It is also the angle made by the axes of the two circles. Thus the spherical angle E P F is the angle made by the planes P E Q and P F Q, or the angle made by tangents to the circles drawn through P, or the angle U O A.

The angle made by two straight lines drawn from the centre (as O A and O B) is often confounded with the arc (A B) which that angle marks out on the sphere. When this causes any confusion, which at first it will sometimes do, instead of each arc mentioned, read its angle: thus for the arc A B read the "angle subtended by the arc A B" or A O B. Thus when we say that the angle made by two great circles is the arc intercepted between their poles, we mean not to equate the angle to the length of an arc, but to the angle which that arc subtends at the centre.

The following propositions are essential to the doctrine of the sphere in geography and astronomy; they may be easily proved, and will serve as exercises in the meaning of the preceding terms:—

1. If the poles of a first circle lie upon a second, the poles of the second will also lie upon the first.

2. If a sphere be made by the revolution of a semicircle round its diameter, the diameter will be an axis, the middle point of the semicircle will describe the primary, all other points will describe parallels, and every position of the generating circle will be a secondary.

3. If a point on a sphere be distant from each of two other points (not opposite) by a quadrant of a great circle, the first point must be a pole of the great circle which joins the second and third.

4. The arc of a parallel (as E F) is found from the corresponding arc of the primary (A U) by multiplying the latter by the cosine of the angle (F O A) which is subtended by the intercepted arc (A F) of the secondary.

5. The surface of the zone intercepted between any two parallels is the rectangle contained under the circumference of the primary and the perpendicular distance between the parallels.

6. The surface of a lune contained between two great circles is such a proportion of the whole surface of the sphere as the angle contained between the two great circles is of four right angles.

7. The part of a lune contained within any zone made by two of its parallels (as E F U A) is such a proportion of the whole zone as the angle of the circles forming the lune is of four right angles.

We are now to show the method of Co-ordinates by which points in the sphere are ascertained, and their relative positions described. Take any great circle C U A B, and choose any point U as an origin, and either direction to be that in which arcs are measured. Say for instance that U A, in preference to U C, shall be the direction in which arcs are measured. The position of any point in this great circle is then ascertained simply by determining its distance from U, since there is a tacit understanding as to the direction in which that distance shall be measured. If we give a name to that distance, be it longitude, right ascension, or any other, the point whose right ascension (if it be right ascension) is 80° means the point which is at 80° distance from U in the direction U A. Again, if we wish to describe any other point, not in the great circle chosen, as F: through F draw a secondary to the great circle (P F A Q), then the point F will be known as soon as A is described, in the manner just laid down, and also as soon as the arc A F is given, and the pole towards which it is measured. These two co-ordinates, U A and A F, when described in magnitude and direction, form a complete description of the position of the point F on the sphere; and the angles subtended by U A and A F are generally used instead of U A and A F.

For the first steps of the application of spherical geometry to astronomy, see the next article.

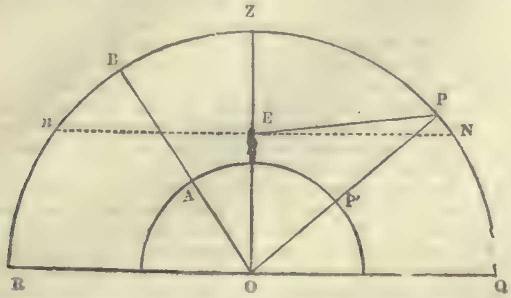
SPHERE, DOCTRINE OF THE. This phrase is generally used to signify the application of the simple geometrical notions in the article Sphere to geography and astronomy. It comes between spherical trigonometry and those two sciences, being merely the explanation of the circumstances under which the former is to be applied to the latter, and the nomenclature which is employed to facilitate explanation.

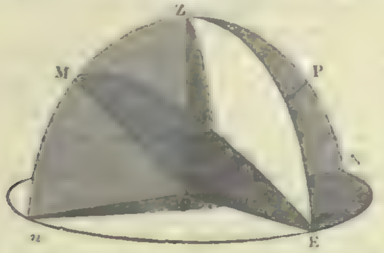
In geography the end is almost gained when a distinct notion is acquired of the meaning of the terms terrestrial latitude and terrestial longitude, generally abbreviated into latitude and longitude. These are only names given to a pair of spherical co-ordinates as described in Sphere, the axis of rotation of the earth furnishing the means of prescribing the necessary data. The earth revolves round an axis, say P Q (see the diagram in Sphere), and the great circle perpendicular to that axis is the *equator* (C U A B). An arbitrary point U is chosen as an origin; and P being the pole which is called north, U A is the east direction and U C the west. The English choose the point U in such a way that the secondary P U passes through the Observatory at Greenwich: the French pay the same compliment to their Observatory at Paris, and so on. The co-ordinate U A (or its angle) is called longitude, east or west according as it falls; and the co-ordinate A F (or its angle) is called latitude, north or south according to the pole towards which it is directed. Thus the place F (P U passing through Greenwich) would be described as in longitude U A east of Greenwich, and F A of north latitude; but if the fundamental secondary, P U, be moved any number of degrees to the east, every east longitude must be diminished and every west longitude increased as much; and all places which the secondary passes over in the transfer, must have the names of the directions of their longitudes changed, and take for their new longitudes the excesses of the angle of transfer over their former longitudes. Again, longitude might be measured all the way round in one direction: thus D, instead of being described as in U C of west longitude, might be considered as in 360° − U C of east longitude.

There are few problems of much interest connected with geography merely; and it must be remembered that the common terrestrial globe, with its brazen secondary to the equator (called a meridian, very incorrectly, except as meaning that it *may be made* a meridian to any place), its ecliptic, and figured horizon, is almost as much a representative of the sphere of the heavens as of the earth; and the most useful problems are those in which the sphere is used conjointly in these capacities. But, merely to show what we asserted at first, that the description and nomenclature which are called the doctrine of the sphere are nothing but the connecting link of geography, &c., and spherical trigonometry, let us ask the following question:—Given a table of latitudes and longitudes, required the distance between two places mentioned? Let D and M be the places (see diagram in Sphere), then P D is the co-latitude of D, or 90° − lat. of D, and P M (on account of M's south latitude) is 90° + lat. of M; while the spherical angle, D P M (which is the angle of the arc A C), is, on account of the longitudes being of different names, the sum of the longitudes of D and M. Hence, if D and M be joined by the arc of a great circle, we have given (from the tables) two sides and the angle included, in the spherical triangle D P M. From these data the third side, D M, can be found, in degrees, &c.: convert this into miles, at the rate of 69 miles to a degree (which is accurate enough for the purpose), and the result will be the distance required.

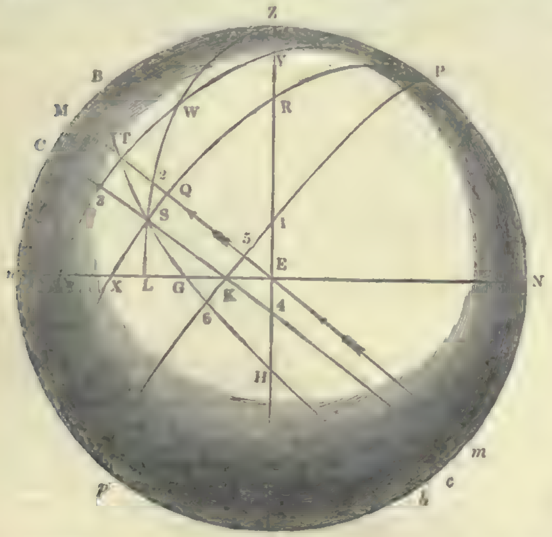
We now make the passage from the terrestrial to the celestial sphere. The latter is a fiction, derived from the impossibility of distinguishing the distances of the heavenly bodies, on which account they all seem at the same distances, on a sphere so great that the earth, its centre, is but a point in comparison. But it must be remembered that the appearances of the heavenly bodies conform themselves to this fiction, so that the development of the consequences of the latter amounts to an explanation of the phenomena of the heavens. And first, the rotation of the earth from west to east gives to the sphere of the heavens an apparent motion from east to west, round an axis which is obtained by lengthening the axis of the earth. The point of the heavens which answers, for the moment, to the spectator's position on the earth, is that point which is directly over his head, or his *zenith*. And since the spectator is not exactly at the centre of the celestial sphere, we give the following diagram, illustrative of the manner in which the effect of this misplacement is destroyed by the largeness of the sphere.

The eye of the spectator is at E, and his zenith-line is O′Z. The smaller circle is a section of the earth, and the larger of the sphere of the heavens. The figure is drawn of dimensions so false, that the sphere of the heavens is represented about as well as a common orrery represents the solar system. The Horizon is the small circle drawn perpendicular to O Z through N S; the altitude of the pole of the heavens (P′ being that of the earth) is the angle N E P. Now suppose the earth and the spectator to diminish until they cannot be distinguished from the point O, the sphere of the heavens remaining the same. All angles at O remain unaltered: the altitude of the pole of the heavens becomes Q O P, equal to the angle A O E, the latitude of the spectator, and the horizon of the latter coincides with the great circle drawn through R Q perpendicular to O Z. The great circle, Q P Z R, passing through the pole and the zenith, is the *meridian;* the secondary to the horizon perpendicular to the meridian is the *prime vertical.* We here exhibit a skeleton of the sphere, showing *n* M Z P N, half the meridian; N E *n*, the horizon (N, E, *n*, its north, east, and south points); Z E, the prime vertical; a portion of P O, the axis; E M, the equator, perpendicular to the axis.

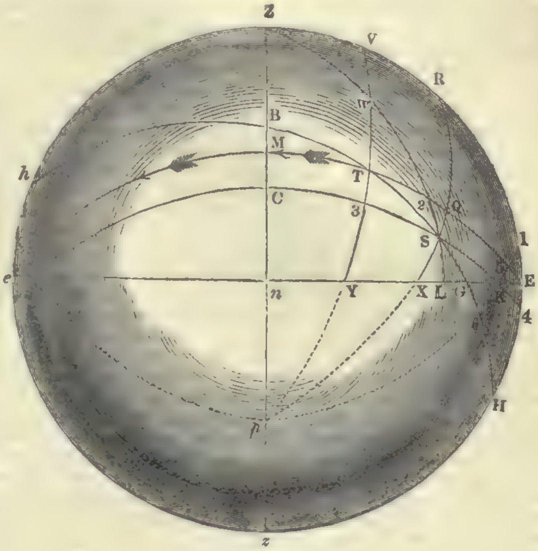


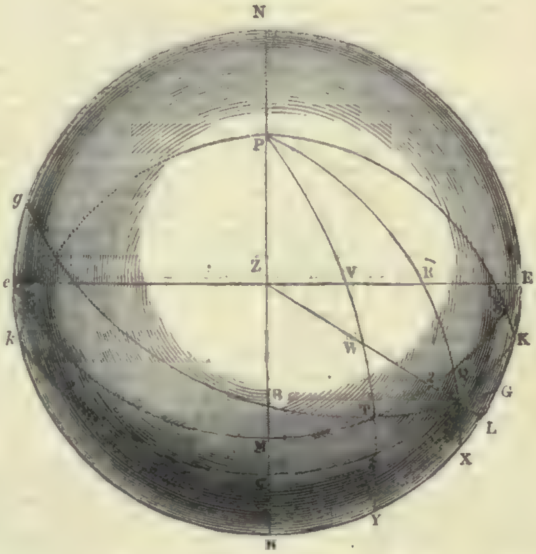


We now give three positions of the sphere, differing only in the manner of projecting the figure. Each one represents the state of the heavens some two or three hours before noon in an October morning, in a latitude somewhat greater than our own. The first figure is projected on the plane of the meridian; that is, the meridian is the circle which bounds the view of the sphere. The second is projected on the prime vertical; the third, on the horizon.



The diagrams have many letters and numerals which are useless, except in tracing the affinities of the figures. The meridian, *n* P Z N; the prime vertical, Z E *z*; the horizon, *n* E N, and its poles, the zenith and nadir, Z and *z*; the equator, M E *m*, and its poles P and *p* (which are called *the* poles, from their importance), are supposed to be well known. The reader who is new to the subject should learn to see the following propositions *in each of the figures*, namely:—the poles of the meridian are the east and west points of the horizon; the poles of the prime vertical are the north and south points of the horizon; the equator and prime vertical make an angle equal to the latitude of the place of observation (which is P N, or the angle of P N); the equator and horizon make an angle equal to the colatitude (90°—lat.) of the place of observation; a star which is distant from the north pole by less than the latitude of the place of observation can never set nor go below the horizon (it is called a *circumpolar* star).





The diurnal motion carries the sphere round the axis in the direction of the arrows marked upon the equator. The meridian, horizon, and prime vertical, must be considered as detached from the sphere, and not moving with it. Every point of the sphere describes a small circle parallel to the equator: and all stars which are at the same distance from the pole describe the same small circle. The whole revolution takes place in what is called a *sidereal* day [TIME], about four minutes less than the *mean solar day* shown by a good clock. A secondary to the equator describes angles uniformly about the pole at the rate of 360° to 24 sidereal hours, or 15° to 1 sidereal hour. [ANGLE.] Hence if we would know how long it will be before the diurnal motion will bring a star at K into the position S, we must turn the angle S P K, which is measured by the arc Q 5, into sidereal time at the rate of 15° to 1^h, and then turn the sidereal time so obtained into common clock time, at the rate of about 23^h 56^m of clock time to 24^h of sidereal time. For purposes of general explanation, the two species of time may be confounded. The sidereal day is always made to begin when a certain point of the equator, presently to be noticed (the vernal equinox), comes on the south side of the meridian, and the hours are measured on to 24^h.

We shall now explain the systems of co-ordinates which are made use of in describing the positions of stars.

1. *Horizontal System. Altitude and Azimuth.*—In this case the horizon is the primitive circle employed; its north point, N, is the origin, and the position of a point W is determined by its azimuth, N I, and its altitude, L W; Z W L being a secondary to the horizon. Since the altitude and azimuth are reckoned by means of a fixed circle, both

are perpetually changing their values for any one star. The following assertions will serve to try the reader's comprehension of these terms:—points on the north side of the meridian are in azimuth 0°, on the south side in azimuth 180°; the zenith has all azimuths, and every other point of the east side of the prime vertical 90° of azimuth; the altitude of a star which sets is greatest when it is on the meridian; the meridian altitudes of a circumpolar star are the greatest and least of all its altitudes, and their half sum is always the latitude of the place of observation. [ALTITUDE; AZIMUTH.]

2. *Equatorial System. Right Ascension and Declination.*—The primitive circle here is the equator; the point of the equator called the vernal equinox (presently described) is the origin, and the direction of the sun's motion from west to east is the direction in which *right ascension* is measured. In the diagrams T is not the vernal, but the autumnal equinox, the point opposite to the vernal equinox, consequently T has 180° of right ascension, and so have W, V, and all points on the same half of the secondary PWT. The other co-ordinate, *declination*, is measured on the secondary to the equator north or south according to its direction: thus S has for its right ascension 180° + TQ, and QS of south declination; while R has the same right ascension, and QR of north declination. The secondaries to the equator are called *hour-circles*, and the difference of the right ascensions of two stars is the angle made by their hour-circles: thus the angle QP5, measured by the arc Q5, is obviously the difference of the right ascensions of the point R and 1. The equator moves with the sphere, so that the right ascension and declination of a star remain the same, as long as it moves only with the diurnal motion. The right ascension is generally expressed in time, as before described; and the following assertions will serve for exercise in the meaning of these terms:—the sidereal day beginning when the vernal equinox is on the meridian, the right ascension of any star, turned into time, expresses the moment of the sidereal day at which that star will be on the meridian; when the vernal equinox is on the meridian of Greenwich, the longitude of any place, measured eastwards, is the same as the right ascension of a star which is on the meridian of that place; the meridian altitude of any star, diminished by its declination (if north), or increased by its declination (if south), is the co-latitude of the place of observation; every star which has the same declination as the place of observation has latitude, passes directly over the head of the spectator at that place; the time of rising of a star, and the time during which it remains above the horizon, depend solely upon the declination, and not at all upon the right ascension. [RIGHT ASCENSION; DECLINATION.]

3. *Ecliptic System. Celestial Longitude and Latitude.*—The ecliptic (BTS*b*) is the circle which the sun appears to describe in the course of a year, the direction of this *orbital* motion being from west to east. One half of it is north, the other half south, of the equator; and the point of the equator in which the ecliptic cuts it, and through which the sun passes when it leaves the southern and enters the northern part of the ecliptic, is the *vernal equinox*, the opposite point being the autumnal equinox. Consequently, T, as drawn, is the autumnal equinox, for motion from west to east, or in the direction BTS, makes the sun pass from the northern to the southern side of the equator. In this system of co-ordinates the ecliptic is the primitive circle, the vernal equinox is the origin, longitude is measured from west to east on the ecliptic, and latitude north or south, as the case may be, is measured on a secondary to the ecliptic drawn through the star. In fact, celestial longitude and latitude are to the ecliptic precisely what right ascension and declination are to the equator. The *obliquity* of the ecliptic is the angle made by the equator and the ecliptic; and the secondaries to the ecliptic, drawn through the vernal and autumnal equinoxes, are the equinoctial and solsticial colures. [LONGITUDE AND LATITUDE.]

A complete understanding of all these terms makes the comprehension of the globe easy, and also the application of spherical trigonometry to those who know the latter science. We now describe the diagrams, in order to point out how such applications are made. The point S is the sun, of course in the ecliptic; its right ascension is 180° + TQ, its declination QS south, its longitude 180° + TS, its latitude 0°, its azimuth NL, its altitude LS, its *hour-angle* (a name given to the angle made by the hour-circle of a star with the meridian) SPM, measured by MQ. The parallel to the equator CSK*c* would be the diurnal path of the sun, if it continued at the point S of the ecliptic; but as the sun has a slow motion of its own towards K, it is not strictly (though very nearly) correct to say that, for the day in question, the sun continues in the parallel. Hence we may say, without sensible error, that the sun moves over *c*K during half the night, and through KC during half the day. It rises when at the point K, and the angle KPS, turned into time, shows the sidereal time elapsed since the rising, while the angle SPM shows the time which is yet to elapse before noon. As to the time of the year, observe that the sun was at the autumnal equinox T on the 21st of September, since which time it has moved over TS, independently of the diurnal rotation of the sphere. We see then what is meant by saying that the diagram represents some morning in October. The use of the globe is thus explained, as far as setting it for any hour and day is concerned. The pole P must first be elevated until the elevation is equal to the latitude of the place, the sun must then be put in its proper place in the ecliptic for the time of the year, and its hour-angle must then be made to represent the time which is wanted of noon, or has elapsed since noon. All this on the globe is done without attending to the distinction of sidereal and solar time, which need hardly be attended to when no greater degree of accuracy is wanted than can be obtained on a globe. We now refer the reader to works on the use of the globes, and shall conclude this article by a few indications of the mode of applying spherical trigonometry.

To find the time of sunrise, observe that in the spherical triangle PKN, right-angled at N, we have PK given, being 90° + the sun's declination, and also PN, the latitude of the place of observation. Hence the angle KPN can be found, which being turned into sidereal time, gives a good approximation to the time of sunrise, refraction and the sun's proper motion being neglected.

Given SL the sun's altitude, and the latitude of the place; required the time of day. In the triangle SZP, we now know ZS the sun's co-altitude, SP which is 90° + declination, and ZP the co-latitude of the place. Hence the angle SPZ can be found, and thence the time from noon. If S, instead of the sun, were a known star, the question would be solved in the same way, except that the sun's hour-angle is no longer SPZ, but that angle increased or diminished by the difference of the right ascensions of the sun and star.

Two known stars, W and S, are observed to be in the same circle of altitude SWL at a given place; required the time of day. Here PW and PS, the co-declinations of the stars, are known, and also the angle WPS, which is the difference of their right ascensions; hence in the triangle SWP the angle SWP can be found, and thence its supplement, the angle ZWP. Then, in the triangle WZP, we know the angle ZWP, PW the co-declination of the star W, and ZP the co-latitude of the place: whence the angle WPZ can be found; and thence, by comparison of W with the sun, the time of day.

For the actual applications we must refer to mathematical works on astronomy.

SPHERICAL ABERRATION. If a lens or mirror could accomplish all that we should desire in it, it would refract or reflect rays diverging from or converging towards a point so that the directions of the refracted or reflected rays should accurately pass through a point. This however can in general be only approximately effected; and the failure of the rays to pass accurately through a point is termed *aberration*. It depends partly on the form of the surfaces, partly on the compound nature of light itself. The former is termed *spherical*, the latter *chromatic aberration*. Spherical aberration is of course the only kind which exists in the case of a mirror. For the formulæ relating to the spherical aberration of lenses and mirrors, see LENS and SPECULUM.

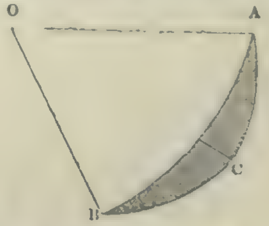
SPHERICAL ANGLE. [SPHERICAL TRIGONOMETRY, &c.]

SPHERICAL EXCESS. [SPHERICAL TRIGONOMETRY, &c.]

SPHERICAL TRIANGLE. [SPHERICAL TRIGONOMETRY, &c.]

SPHERICAL TRIGONOMETRY, SPHERICAL TRIANGLE, SPHERICS. We shall confine ourselves in the present article to such a collection of the properties of a spherical triangle as may be useful for reference, referring for demonstration to the treatise on the subject in the 'Library of Useful Knowledge,' and to that on Geometry; adding to the former nothing but a shorter mode of obtaining Napier's Analogies.

By a spherical triangle is meant that portion of the sphere which is cut off by three arcs of great circles, each of which cuts the other two as ABC. It is now usual, however, to consider the spherical triangle as a sort of representative of the solid angle formed at the centre of the sphere by the planes AOB, BOC, COA, as follows:—The arcs AB, BC, CA, are the measures of the angles AOB, BOC, COA, and are used for them: the spherical angles BAC, ACB, CBA are by definition the angles made by the planes BOA and AOC, AOC and COB, COB and BOA. The sperical triangle then has six parts corresponding in name to the six parts of a plane triangle; but a *side* of it means the angle made by two straight *lines* of a solid angle, while an *angle* of it refers to the angle made by two *planes* of the solid angle.



Throughout this article we shall designate the angles by A, B, C, the sides opposite to them by *a*, *b*, *c*; the half sum of the sides by *s*. And by A′, B′, C′, *a*′, *b*′, *c*′, we mean the supplements of A, B, &c., so that A + A′ = 180°, *a* + *a*′ = 180°, &c. No triangle is considered which has either a side or an angle greater than 180°.

Three circles divide the sphere into eight spherical triangles. Of these four are equal and opposite to the other four, with which they agree in every respect but one [SYMMETRICAL] with which we have nothing here to do. Of the four which are distinct, if ABC be one, there are three others thus related to it: the first has for its sides *a*, *b*′, *c*′, and for its angles A, B′, C′,; the second has *a*′, *b*, *c*′, for sides, and A', B, C', for angles; the third has a', b', c for sides, and A', B', C, for angles. Hence every spherical triangle has another, with one side and its opposite angle remaining unchanged, and all the other parts changed into their supplements.

Again, if the three circles be taken which have A, B, and C for their poles, the intersections of these new circles are themselves the poles of AB, BC, and CA; and, of the eight new triangles thus formed, each one has all its *angles* supplemental to the *sides* of its corresponding triangle in the first set, and all its *sides* supplemental to the *angles*. Thus there exists a triangle which has the sides A', B', C', and the angles a', b', c'; which is called the supplemental triangle of that which has a, b, c, for sides, and A, B, C, for angles. Hence if, in any general formula, sides be changed into supplements of angles, and angles into supplements of sides, the result is also a general formula.

Any two sides of a spherical triangle are together greater than the third, and the sum of the three sides is not so great as 360°. Any two angles of a spherical triangle are together less than the third angle increased by 180°, and the sum of the three angles is more than two, and less than six, right angles. And the greater side of a spherical triangle is opposite to the greater angle; and the sum of two sides is greater than, equal to, or less than, 180°, according as the sum of the opposite angles is greater than, equal to, or less than, 180°.

The formulæ for the solution of a spherical right-angled triangle are six in number. Let C be the right angle, and let c be called the *hypothenuse*, as distinguished from a and b, which are still called *sides*. [CIRCULAR PARTS.]

1, 2. The cosine of the hypothenuse is equal to the product of the cosines of the sides, and of the cotangents of the angles:

$$\cos c = \cos a \cos b;\quad \cos c = \cot A \cot B.$$

3. The sine of a *side* is the sine of the hypothenuse into the sine of the *opposite* angle:

$$\sin a = \sin c \sin A;\quad \sin b = \sin c \sin B.$$

4. The tangent of a side is the tangent of the hypothenuse into the cosine of the included angle:

$$\tan a = \tan c \cos B;\quad \tan b = \tan c \cos A.$$

5. The tangent of a side is the tangent of its opposite angle into the side of the other side:

$$\tan a = \tan A \sin b;\quad \tan b = \tan B \sin a.$$

6. The cosine of an angle is the cosine of its opposite side into the side of the other angle:

$$\cos A = \cos a \sin B;\quad \cos B = \cos b \sin A.$$

These formulæ are sufficient for every case. Name any two out of the five a, b, c, A, B (C being a right angle), and in the preceding six formulæ, by repetition ten, will be found those two combined with each of the other three. Thus, having given a side a and its adjacent angle B, we find the other parts from

$$\tan b = \tan B \sin a,\ \tan c = \frac{\tan a}{\cos B},\ \cos A = \cos a \sin B.$$

These formulæ should be committed to memory: the abbreviation, so called, described in CIRCULAR PARTS, is only an expeditious mode of wasting time.

When all the angles are oblique, the principal formulæ are as follows (in most cases we give only one, those for other sides, &c., being easily supplied):—

1. $\dfrac{\sin A}{\sin a} = \dfrac{\sin B}{\sin b} = \dfrac{\sin C}{\sin c}$; or the sines of sides are to one another as the sines of their opposite angles.

2. $\cos c = \cos a \cos b + \sin a \sin b \cos C$.

3. $$\cos\frac{C}{2} = \sqrt{\frac{\sin s\ \sin(s-c)}{\sin a\ \sin b}}$$

$$\sin\frac{C}{2} = \sqrt{\frac{\sin(s-a)\ \sin(s-b)}{\sin a\ \sin b}}.$$

4. $$\tan\frac{C}{2} = \sqrt{\frac{\sin(s-a)\sin(s-b)}{\sin s\ \sin(s-c)}} = \frac{M}{\sin(s-c)};$$

where $M = \sqrt{(\sin(s-a)\ \sin(s-b)\ \sin(s-c) \div \sin s)}$.

5. $$\tan\frac{A+B}{2} = \cot\frac{C}{2}\,\frac{\cos\frac{1}{2}(a-b)}{\cos\frac{1}{2}(a+b)}$$

$$\tan\frac{A-B}{2} = \cot\frac{C}{2}\,\frac{\sin\frac{1}{2}(a-b)}{\sin\frac{1}{2}(a+b)}.$$

6. $\cot a \sin c = \cos c \cos B + \sin B \cot A$.

7. $\tan\theta = \sin\frac{1}{2}C\sqrt{\sin a\ \sin b} \div \sin\frac{1}{2}(a-b)$,
gives $\sin\frac{1}{2}c = \sin\frac{1}{2}(a-b) \div \cos\theta$.

8. $\sin\theta = \sin\frac{1}{2}C\sqrt{\sin a\ \sin b} \div \cos\frac{1}{2}(a-b)$,
gives $\cos\frac{1}{2}c = \cos\frac{1}{2}(a-b)\cos\theta$.

The formulæ (5) which are called Napier's Analogies, may be demonstrated more easily than in the usual way, as follows. First—

$$\tan(\tfrac{1}{2}A \pm \tfrac{1}{2}B)\,.\tan\tfrac{1}{2}C = \frac{\tan\frac{1}{2}A\tan\frac{1}{2}C \pm \tan\frac{1}{2}B\tan\frac{1}{2}C}{1 \mp \tan\frac{1}{2}A\tan\frac{1}{2}B}$$

$$\text{from (4) } \tan\tfrac{1}{2}A\tan\tfrac{1}{2}B = \frac{\sin(s-c)}{\sin s},\ \&c.$$

$$\tan(\tfrac{1}{2}A \pm \tan\tfrac{1}{2}B)\,.\tan\tfrac{1}{2}C = \frac{\sin(s-b) \pm \sin(s-a)}{\sin s \mp \sin(s-c)}.$$

[TRIGONOMETRY.] $\tan(\tfrac{1}{2}A + \tfrac{1}{2}B)\,.\tan\tfrac{1}{2}C = \dfrac{2\sin\frac{1}{2}c\ \cos\frac{1}{2}(a-b)}{2\sin\frac{1}{2}c\ \cos\frac{1}{2}(a+b)}$

since $2s - a - b = c$. Hence the first of (5) easily follows, and the second in a similar manner.

The formula (6) is not easily remembered, except by the following:—Write the sides in any successive pairs, as ab, bc, ca, or ac, cb, ba: change the last three into the corresponding angles giving ab, bc, CA, or ac, cB, BA; remembering the formula cos ÷ sin = cot make the middle terms cosines, those on the right and left sines, and those on the extreme right and left cotangents. We have then—

$$\cot a \sin b = \cos b \cos C + \sin C \cot A,$$

which is a case of the formula in question.

We now proceed to the different cases of triangles, observing that these may be taken in pairs, owing to the property of the supplemental triangle. Thus, suppose it granted that we can solve the case of finding the three angles when the sides are given, it follows that we can solve that of finding the three sides from the three angles. For, if A, B, and C be given, find the *angles* of the triangle whose sides are A', B', and C'. If a', b', and c' be these angles, then a, b, c are the sides of the original triangle. Nor is it worth while to separate the several cases, since it generally happens that out of each pair one is of much more frequent occurrence than the other.

Case 1.—Given the three sides, to find the three angles. If one angle only be wanted, one of the formulæ (3) answers as well as anything. If all three angles be wanted, the shortest way is to calculate M from

$$M = \sqrt{\{\sin(s-a)\ \ \sin(s-b)\ \ \sin(s-c) \div \sin s\}}$$

and then the angles from

$$\tan\tfrac{1}{2}A = \frac{M}{\sin(s-a)},\ \tan\tfrac{1}{2}B = \frac{M}{\sin(s-b)},\ \tan\tfrac{1}{2}C = \frac{M}{\sin(s-c)}$$

Supplement.—Given the three angles, to find the three sides. Make the supplements of the given angles sides, calculate the three angles, and the supplements of the last three angles will be the sides required.

Case 2.—Given two sides (a and b), and the included angle C, to find the remaining parts. If all the parts be wanted, calculate $\frac{1}{2}(A+B)$ and $\frac{1}{2}(A-B)$ from (5), and then find A and B by addition and subtraction: lastly, find c from one of—

$$\sin c = \sin b\,\frac{\sin C}{\sin B},\ \sin c = \sin a\,\frac{\sin C}{\sin A};$$

or from both, which will be a verification. But if the remaining side only be wanted, use the formula (7) or (8), which gives this third side at once, by means of the subsidiary angle θ. Or from the extremity of the shorter side given (say a), let fall a perpendicular arc z on b, dividing b into x and y. Then—

$$\tan x = \tan a \cos C,\quad \sin z = \sin a \sin C$$

$$y = b - x,\quad \cos c = \cos z \cos y.$$

Supplement.—Given a side (c) and the two adjacent angles (A and B); required the remaining parts. Make A' and B' the sides of a triangle, and c' the included angle; find C' the remaining side, and a' and b' the remaining angles. Then C is the remaining angle of the original triangle, and a and b are the remaining sides. To find the remaining sides alone, the following formula may be used:

$$\tan\frac{a+b}{2} = \tan\frac{c}{2}\cdot\frac{\cos\frac{1}{2}(A-B)}{\cos\frac{1}{2}(A+B)}$$

$$\tan\frac{a-b}{2} = \tan\frac{c}{2}\cdot\frac{\sin\frac{1}{2}(A-B)}{\sin\frac{1}{2}(A+B)}$$

Case 3.—Given two sides (a and b) first both less than a right angle, and an angle opposite to one of them (A); required the remaining parts. This case may afford no solution at all, or may give two solutions; it is therefore sometimes called the ambiguous case. The formula (6) may be used by the usual introduction of a subsidiary angle; but we should recommend a person who is not well practised in the subject to prefer the following simple method:—From the extremity of b which is *not* adjacent to the given angle, drop a perpendicular z on the side c, and let x be the segment adjacent to A. Let $a\hat{}z$ and $b\hat{}z$ be the angles made by a and b with z. And first calculate $\sin b \sin A$; if this be greater than unity, the triangle does not exist; if it be equal to unity, the triangle is right angled at B, and may be treated as a right-angled triangle. But if $\sin b \sin A$ be less than unity, find z from $\sin z = \sin b \sin A$, and x and B from

$$\tan x = \tan b \cos A, \sin B = \sin A \frac{\sin b}{\sin a}.$$

There are two values of B, supplements of each other, both of which are possible answers. Let B be the one which is less than a right angle, and B′ that which is greater.

First, when A is acute and a less than b. Calculate y from $\cos y = \cos a \div \cos z$, and $b^{\wedge}z$ and $a^{\wedge}z$ from

$$\cot b^{\wedge}z = \cos b \tan A, \quad \cos a^{\wedge}z = \frac{\tan z}{\tan a}.$$

There are two triangles which satisfy the data; in the first, $c = x - y$, B′ is the angle opposite to b, and $C = b^{\wedge}z - a^{\wedge}z$; in the second, $c = x + y$, B is the angle opposite to b and $C = b^{\wedge}z + a^{\wedge}z$.

Secondly, when A is acute and a equal to or greater than b. Calculate exactly as in the last case, but there is only one triangle which satisfies the data, namely, the second of the preceding.

Thirdly, when A is obtuse, in which case there is no triangle, unless a be greater than b. Calculate (using A as more convenient)

$$\sin z = \sin b \sin A', \tan x = \tan b \cos A, \sin B = \sin A' \frac{\sin b}{\sin a}$$

Use the value of B which is less than a right angle; calculate $b^{\wedge}z$ and $a^{\wedge}z$ from

$$\cot b^{\wedge}z = \cos b \tan A', \cos a^{\wedge}z = \frac{\tan z}{\tan a}.$$

Then $c = y - x$, and $C = a^{\wedge}z - b^{\wedge}z$.

In the case in which one or both of the sides are greater than a right angle, which rarely, if ever, occurs, it is best to have recourse to one of the adjacent triangles described at the beginning of this article, and to use it in the same manner as the supplementary triangle has been used. It is not however necessary to dwell on this point.

Supplement.—Given two angles (A and B) and a side opposite to one of them (a); required the remaining parts. Let A′ and B′ be the sides of a triangle, and a' the angle opposite to A′. Find C′ the remaining side, and b' and c' the remaining angles; then C is the remaining angle of the original triangle, and b and c the remaining sides.

All the cases would need some subdivision to adapt them to calculation, if it were really often required to solve triangles with very large sides and angles. But in application it generally happens that the reasoning of the previous part of the process is so conducted as to throw the calculation entirely upon triangles which have at least two sides and two angles severally less than a right angle. Divide a great circle into three parts, and we have the extreme limit of a spherical triangle: the sum of its sides being 360°, and the sum of its angles six right angles. But a triangle which should be very near to this limit would be best used in reasoning, and solved in practice, by means of one of the other seven triangles into which its circles divide the sphere. And if one of the sides should be greater than two right angles, the remainder of the hemisphere would be the triangle on which calculation is employed. And it is to be understood that all the formulæ are demonstrated only for the case in which every side is less than two right angles. At the same time we should recommend the beginner to procure a small sphere, and to habituate himself to the appearance of all species of triangles.

The area of a spherical triangle is singularly connected with the sum of its angles, on which alone it depends, the sphere being given. Let any two triangles, however differently formed, have the sum of their angles the same, and they must have the same area. If the angles be measured in theoretical units [ANGLE], the formula is as follows: r being the radius,

$$\text{Area} = r^2 (A + B + C - \pi),$$

which gives the number of square units in the area, the radius being expressed in corresponding linear units. But if the angles be measured in degrees and fractions of a degree, the formula is

$$\text{Area} = \cdot 01745329252\, r^2 (A + B + C - 180).$$

The angle A + B + C − 180° is called the *spherical excess*, and it may be found at once from the sides by the formula

$$\tan^2 \frac{\text{sph. ex.}}{2} = \tan \frac{s}{2} \tan \frac{s-a}{2} \tan \frac{s-b}{2} \tan \frac{s-c}{2};$$

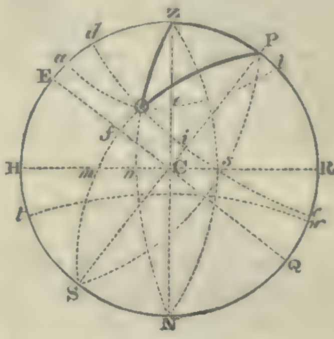
so that the area of a triangle is easily found from its sides. If a spherical triangle were flattened into a plane one, without any alteration of the lengths of its sides, it is obvious that the sum of the angles would undergo a diminution, being reduced to 180°. The angles would not diminish equally; but, if the sphericity of the original triangle were small, or if it occupied only a small part of the sphere, the diminutions which the several angles would undergo in the process of being flattened would be so nearly equal, that it would be useless, for any practical purpose, to consider them as unequal. For a triangle of small sphericity, then, it may be assumed that in being flattened, each of its angles loses one-third of the spherical excess. This proposition is one of considerable use in the measurement of a degree of the meridian.

SPHEROGRAPH, an instrument invented in 1856, for facilitating the practical use of spherics in navigation, &c., being a contrivance for constructing, without dividers or scales, any possible spheric triangle, and reading off the measures of the parts required; thus in most cases saving much time and labour. The degree of accuracy of the instrument is limited only by its size, but it has been found by navigators that circles of 5-inch radius will work any question which arises at sea, sufficiently near for the practical purposes of the navigator.

The description of the instrument will be better understood by giving some general preparatory hints as to the names of the ordinary lines of the sphere.

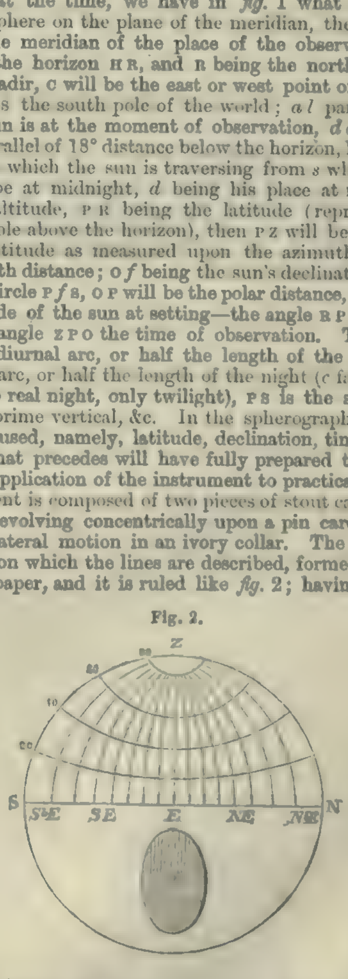
In the following figure, No. 1, the observer is supposed to be at the centre C of a hollow transparent sphere, on which the usual lines are drawn as upon a terrestrial globe. He would see the sun as at O upon the globe's surface amongst these lines. Rejecting all superfluous circles, &c., and confining our description to such parts as affect the sun's position at the time, we have in *fig.* 1 what is called a projection of the sphere on the plane of the meridian, the primitive circle representing the meridian of the place of the observer, H being the south part of the horizon H R, and R being the north, Z will be the zenith, N the nadir, C will be the east or west point of the horizon, P the north pole, S the south pole of the world; *a l* parallel of altitude in which the sun is at the moment of observation, *d c* the sun's declination, *t w* a parallel of 18° distance below the horizon, limiting twilight to the period at which the sun is traversing from *s* where he sets, to *c* where he will be at midnight, *d* being his place at noon; H *d* being the meridian altitude, P R being the latitude (represented by the height of the pole above the horizon), then P Z will be the co-latitude, O *n* the sun's altitude as measured upon the azimuth circle Z *n*; O Z will be the zenith distance; O *f* being the sun's declination as measured upon the hour circle P *f* S, O P will be the polar distance, E Q the equator, Z *s* the amplitude of the sun at setting—the angle R P *s* being the time of sun-set, the angle Z P O the time of observation. The small circle *d s* is the semi-diurnal arc, or half the length of the day, and *s c* the semi-nocturnal arc, or half the length of the night (*c* falling within R *w* there will be no real night, only twilight), P S is the six o'clock hour-circle, Z N the prime vertical, &c. In the spherograph only five terms are principally used, namely, latitude, declination, time, azimuth, and altitude, and what precedes will have fully prepared the mind of the reader for the application of the instrument to practical purposes.

Fig. 1.



The instrument is composed of two pieces of stout card-board, nicely attached, and revolving concentrically upon a pin carefully turned to work without lateral motion in an ivory collar. The upper card has the ruled part, on which the lines are described, formed of stout transparent tracing paper, and it is ruled like *fig.* 2; having only azimuths and parallels of altitude (it has an oval space cut so as to enable the observer to put pencil marks on the under sphere), while the unde

Fig. 2.



one (*fig.* 3) has hour circles and parallels of declination: for of the three parts always given in every spheric triangle, two will fall on either one of the cards, and their intersection is made to touch the third datum as found in the other. We will suppose, in illustration, that we have given the sun's altitude 48°, the declination 10° N., and the apparent time 11 h. A.M., to find the latitude. If we discard all the lines that are not necessary to the working of this question, we shall, in *fig.* 4, have a view of the spheric triangle under consideration, which, had it been merely projected on a plane, must have been worked by computation, thus: in the spheric triangle Z O P we have O Z = zenith distance, O P the polar distance, and Z P O the hour angle, to find Z P the co-latitude, and thence P R the latitude. By the spherograph this question of latitude is answered (simultaneously with numerous other results not asked for in this) by *simply turning the upper sphere on the under*, until the place where the time and declination on the under sphere coincide with some part of the parallel of given altitude on the upper. The instrument is thus said to be set, and the measures of altitude, azimuth, time of sun setting, rising, &c., are at once read off: while without the spherograph the latitude alone would require the following work (and one illustration of its saving of time and labour will suffice):—

Fig. 3.

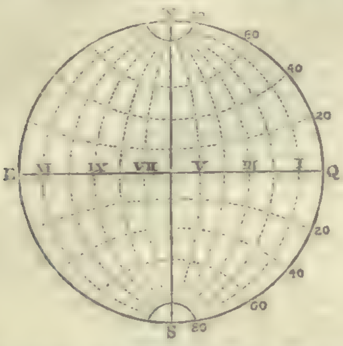


Fig. 4.

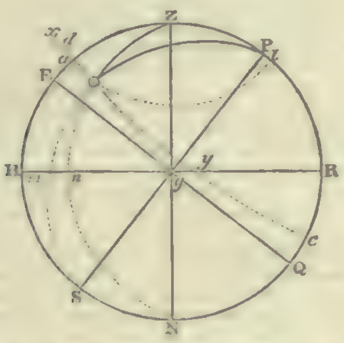


After letting fall a perpendicular in *fig.* 4 from the centre *g* through *o* to *x* [SPHERICAL TRIGONOMETRY], O *d* P will be a right angle, then by circular parts in triangle P Z O find angle Z, thus,—

As sine zenith distance O Z, 42° . co. ar. 0·174489
Is to sine hour-angle P, 15° . . . 9·412996
So is sine polar distance O P, 80° . . . 9·993351

To sine angle Z, 180°—22° 23′ = 157° 37′ = 9·580836

In △ *d* P O find *d* P.

As cotang. polar distance, 80° . co. ar. 0·753681
Is to cosine hour-angle, 15° . . . 9·984944
So is radius . . . . 10·

To tangent side *d* P, 79° 39′ . . = 10·738625 = 79° 39′

In △ *d* Z O find *d* Z.

As cotang. zenith distance, 42° . co. ar. 9·954437
Is to cosine 180°—157° 37′ = 22° 23′ . . 9·965981
So is radius . . . . . . 10·

To tangent of *d* Z, 39° 47′ . . = 9·920418 = 39° 47′

Co-latitude = 39 52
90

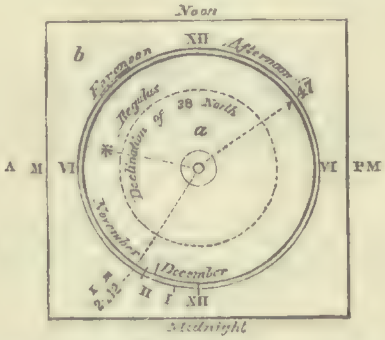
Latitude = 50 8

The spherograph is of different forms, to suit special purposes. Figures 2 and 3 combined, 2 being the upper sphere, represent its general form for latitude, time, azimuth, altitudes, and declination; and it has introduced a new mode of navigating ships in places subject to fogs and haze: for instance, the Montreal traders use it on the Banks of Newfoundland, by substituting azimuth for altitude, in the three things given, when the horizon is entirely invisible, the sun being in sight. It also dispenses with double altitudes, inasmuch as latitude can be as well determined by it from a single observation as from two, rendering all *elapsed* time uncalled for. But it is not our purpose to describe these methods in detail. It seems, however, that a means of so readily finding the position of a fast-sailing steamer when approaching the land is important.

It is well known that one common source of error in working sea observations taken at night, is the liability to mistake the name of a star. This instrument provides a very handy method of correctly finding the name of any star of the first magnitude, even when others around it are obscured. The inventor of the spherograph, Mr. Stephen Martin Saxby, R.N., had noticed that no two stars of the first magnitude had equal declinations in either hemisphere, or were within two or three degrees of each other in that respect. By having a list of such stars and their declinations on the face of the instrument, the name of any star of first magnitude is easily obtained in the following manner:—Using merely approximate data, such as latitude, altitude, and azimuth, we apply them thus: suppose a star has an altitude of about 10°, its true bearing [BEARING] being N.E., the estimated latitude of the place being 43° N.; setting the instrument to the latitude, the intersection of these three elements would on the line of declination be 38¼° N. Reference to the list of stars on the instrument would at once show that this declination could only apply to the star *α* Lyræ.

In working a night observation, the finding of the right ascension is rendered in the spherograph peculiarly simple, and is divested of all liability to error from the occasional fault of adding instead of subtracting, &c. A form of spherograph is prepared for this. (See *fig.* 5.)

Fig. 5.



The inner circle *a* revolves upon a centre-pin connecting it with *b* the under part. On this circle the principal stars are delineated according to their right ascensions, which are measured on its circumference, and their declinations as measured upon a radius. To avoid confusion, we omit, in the above figure, all but Regulus. Suppose at $2^h\ 12^m$ a.m., on the 5th of November, a navigator was desirous of using Regulus as a means of obtaining his latitude, &c. On turning the circle till the date 5th November, marked on it, coincided with $2^h\ 12^m$ marked upon the outer part *b*, he would find that a line through Regulus would cut a point on the part *b* at the distance of $5^h\ 5^m$ from the part of the circle marked Noon. This, then, would be the star's distance from the meridian, and would be used in the common form of spherograph made up of *figs.* 2 and 3, as if it were time by the sun. Thus night observations are rendered as easy as those taken by day.

There is another peculiarity of the instrument. Heavy southerly gales in the English Channel, when they clear up, generally do so by the clouds breaking in the N.W. to N., so that the polar star is generally about the first star visible. At such times, the mariner eagerly attempts to obtain his latitude, and the form of spherograph *fig.* 5, is a very great convenience. Suppose he have obtained an altitude of the polar star = 50° 5′ at $2^h\ 12^m$ a.m. of 5th November; having set the date to the hour as before, the polar index engraved on the circle will point to some one of the figures engraved round the circle on the part *b*; in this instance it would be to 47′ subtractive: then 50° 5′ − 47′ = 49° 18′, the true latitude, to the nearest mile. The readiness of the method admits of increased number of observations; and, consequently, by using the *means* of such observations, the present prevailing error from the indistinctness of the horizon is greatly diminished.

We shall only notice one other use of the spherograph as greatly curtailing labour of computation—namely, in lunar observations. The lines on *fig.* 6 are thus obtained (and here, again, a knowledge of the principles on which the lines are constructed is not at all necessary to the successful use of it):—

Taking advantage of the circumstance that refraction varies nearly as the tangent of the zenith distance, and as tan. 45° = radius, we take, in the projection for refraction, the radius as the refraction at 45°

zenith distance. It fortunately happens that 58″·4, the number of seconds in the refraction at 45°, nearly corresponds with the number of minutes in the mean horizontal parallax. The same diagram does therefore for both parallax and refraction, substituting seconds for minutes.

In the following figure (6), therefore, CA, or CM, or CD = moon's horizontal parallax; MCS = apparent distance between the sun and moon, M being the moon's place in the figure and S the sun's; or the arc MS = apparent distance. MZ = the moon's zenith distance, or, as every part of the small parallel of altitude, FE, is equally distant from M, CH on the line of sines will equal the moon's altitude.

And again, ST will be the sun's zenith distance, and therefore CK on the line of sines will equal the sun's altitude, AD being the moon's horizon and hr the sun's; HE will be the moon's parallax in altitude;

Fig. 6.

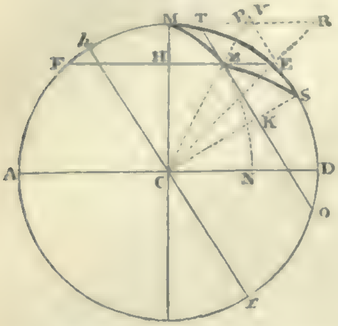


Fig. 7.

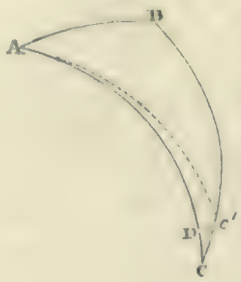

and HE : CD :: cos. ED : radius, or the moon's parallax in altitude = $\frac{\text{hor. pax.} \times \text{cos. moon's alt.}}{\text{radius}}$.

And in the orthographic projection of the lunar triangle MSZ on a scale where radius is = moon's hor. parallax, or CD, the angle M is the angle at the moon corresponding with the angle C in the usual lunar construction, as in *fig.* 7; and CN (the distance of the orthographic great circle MN passing through Z, where the sun's and moon's horizons coincide) is the cosine of this compared with radius CD. But CD : CN :: HE : HZ; or HZ is the correction for parallax = $\frac{CN \times HE}{\text{radius}}$, and is measured from HZ by the scale of chords from the nature of the projection. (In *fig.* 7, CC′ : CD :: rad. : cos. C, CC′ being the moon's parallax in altitude, and CD the correction for parallax.) In *fig.* 6, moreover, MR = tangent of moon's zenith distance, in seconds for alt. 45°; MP, correction for moon's refraction in seconds; SV = correction for sun's refraction in seconds. Such being the principles on which this part of the spherograph is constructed, the following is the form of each of the parts:—The under sphere has its line MC crossed by parallel circles drawn to the scale of sines, or on the orthographic projection; these are again crossed by lines parallel to MC, CD being divided into 60 parts by the line of chords (being very nearly 58″·4 of refraction at 45°, as above).

The practical use of the spherograph in correcting a lunar distance may be thus briefly illustrated: suppose, for example, the apparent distance given = 72°, the moon's altitude = 26°, the sun's altitude = 32°, and the reduced horizontal parallax = 59′. Moving the circles concentrically until M and S are moved 72° apart in *fig.* 6; = the apparent distance, where the two horizons AD and OT cut each other, will give a point which, counting the vertical lines from MC, each will be one minute of correction (as read upon CD); this correction, multiplied by a number taken from a small table printed on the back of the instrument, gives at once a correction for the distance, thus:—

The number read on CD = ...	24′
The tabular multiplier = . . .	·952
	3808
	1904
	22·818 = 22′ 51″
The apparent distance	72° 0′ 0″
Sum of corrections (subtractive) . . .	22 51
True distance by spherograph . . .	71 37 9
Elaborate logarithm calculation gives . .	71 37 8
	1″ error.

When the intersection of the horizons falls on the right of MC, the correction is subtractive; when to the left, it is additive. The spherograph is especially useful to check observations when worked out by logarithms, and imparts confidence to a navigator. A little work published by Longman and Co., called 'Calculation and Projection of the Sphere,' plainly illustrates the general mode of spheric construction.

SPHEROID, a name given to the class of surfaces which are formed by the revolution of an ellipse about either its longest or shortest diameter. When the longer diameter is the axis, the spheroid is called *prolate;* when the shorter, *oblate.* The earth is an oblate spheroid, or very near indeed to such a figure: hence the oblate spheroid is of much more importance than the prolate one. The general properties of the spheroid are either those which belong to it as particular cases of SURFACES OF THE SECOND DEGREE, or those which are useful in geodesy, and which belong more to the generating ellipse than to the surface.

SPHEROIDAL CONDITION OF LIQUIDS. [EBULLITION.]

SPHINX. The name applied in glyptic art to the combinations of lions' bodies with other forms; that with a human head being called androsphinx, with a ram's criosphinx, and with a hawk's hieracosphinx. They appear to have been derived from Egypt, where they were sculptured as symbolical representations of kings and queens, and they expressed in the hieroglyphic texts the idea of *neb* lord, or *akar* victory, or the sun on the horizon. In Egyptian art they are represented couchant, with a human head, the portrait of the monarch they personify; and recent excavations at Tanis have shown that they are as old as the 17th dynasty of Shepherds, the king Apepa or Aphophis being thus represented. In Egyptian art they are rarely winged, the only example being the sphinx of the queen Mutnemt at Turin; Thothmes III. and other monarchs, even the young Alexander and Ptolemies are personified as sphinxes, and there are some small sphinxes in European collections, as one in the Louvre, at Paris, of Rameses II., 23 feet long, of a block of red syenite, and a black granite sphinx of Amenophis III. at St. Petersburg; but the largest is that at Gizeh, of 143 feet long and 62 feet high, cut out of the solid rock, and lying about 1960 feet east of the second pyramid. This was called Har-ma-khu, or Harmakhis, "Horus on the Horizon," and adored as a god by Thothmes IV. and Rameses II. It was approached by a staircase and surrounded by a kind of peribolos, having a temple of alabaster and granite attached to it, in which was a well filled with Nile water, into which had been thrown seven statues of green and yellow breccia of the monarch Shafra, or Kephren, the builder of the second pyramid. Winged sphinxes are often seen in Assyrian and Babylonian art, and seem to represent deities or monarchs under this form.

The few remains of Phœnician art show that this people had adopted the form of the sphinx, probably from Egyptian sources, and the Etruscans seem to have derived the same from their oriental connection, their early works of art being often decorated with representations of this monster. The same may be also said of the Greeks and other cognate races, winged sphinxes being a common type in Greece, Lycia, and other localities. At the earliest period of art sphinxes have recurved wings, but on some later monuments they are unwinged. They have the face and breasts of a beautiful but cruel female, the body of a lioness, and sometimes the tail of a dragon. According to the earliest myths, the Sphinx was the daughter of Typhon and Echidna, Orthus or Typhon and Chimæra, and being sent by Juno to punish the Thebans, proposed a fatal riddle or enigma which was solved by Œdipus, and the Sphinx destroyed. Sphinxes are also found in India as the ornaments of temples.

(Mariette, Aug., *Revue Archéologique*, 1860, p. 18-20, 1861, p. 20; Birch, *Mus. Class. Antiq. II.* p. 27; Vyse, *Pyramids, III.* p. 107; Letronne, *Inscr. SPIGELIA MARYLANDICA, Carolina pink, perennial worm-grass, or worm-seed; a perennial herbaceous plant, native of the southern states of the American Union. It is from six inches to two feet high, leaves opposite, sessile, ovate, and acuminate. The root has a short caudex, from which issue numerous fibres; all which parts are of a yellowish colour when first dug up, but become black on drying. It is collected by the Indians, and sold to the white traders, who pack it in casks, or make it up into bales, weighing from three hundred to three hundred and fifty pounds. The odour of the fresh plant is disagreeable, the taste sweetish, slightly bitter, and nauseous. The leaves are less potent than the root, which part consists of woody fibre 82, a peculiar principle like tannin 10; bitter acrid extractive 4; and an acrid resin; also a fixed and a volatile oil. Both the resin and extractive have emetic properties. Spigelia has slight narcotic powers, and in large doses causes vomiting and purging. In America the fresh plant has decided anthelmintic virtues, but it is only useful against the *Ascaris lumbricoides*, or large round worm. In Europe it is little used, having lost much of its power by long keeping. Dr. Barton recommends it as a cure for the infantile remittent fever, which often terminates in hydrocephalus, or water in the head. In such a case it acts beneficially by removing the worms, the irritation of which, when propagated to the brain, gives rise to the more serious disease. But the expulsion of the worms by any other means, and the exhibition of any tonic and astringent, like the tannin of the Spigelia, will prevent their recurrence. [ANTHELMINTICS.]

Spigelia is given in powder, or as an infusion or decoction. It is usually combined with senna or some other purgative, but it is better to give it alone, and follow its administration by a dose of calomel and jalap.

The *Spigelia Anthelmia*, a native of Brazil, which is a much more potent plant, is sometimes mistaken and given for the other. It contains an alkaloid called spigelina, which is volatile, somewhat like nicotina, the effects of which it also resembles, causing formidable narcotic symptoms, to which lemon-juice, sugar, or carbonate of potash is said to be an antidote.

SPINA BI'FIDA, or cleft-spine, is a disease commencing in fœtal life, and which consists in an imperfection of the posterior part of the spinal canal. It is almost always accompanied by an excessive secretion of spinal fluid, and in these cases it may be regarded as a disease of the same kind affecting the spinal canal as that which, existing in the skull, constitutes hydrocephalus. The two are indeed not unfrequently coincident; and spina bifida is sometimes called hydrorachis.

The arch of each vertebra [SKELETON, in NAT. HIST. DIV.] is developed and ossified in two pieces which meet behind in the middle line at the base of the spinous process. This is also developed in two lateral portions which subsequently unite together and with the arch, so as to form the one piece of bone which we find in the adult closing in the back of the spinal canal. This development and union of the arches of the vertebræ goes on during an early period of fœtal life, while the spinal column is growing rapidly, and the fluid of the spinal canal and arachnoid sac is being constantly secreted. If this fluid be secreted in an unnaturally large quantity before any or a part of the arches of the vertebræ are completely ossified, it may exert such pressure upon them as to separate their component parts, and produce a permanent aperture in the back of the spinal canal, through which a sac containing the excess of fluid will protrude. Or if the development and ossification of any or all of the arches take place more slowly than it should, then a secretion of not more than the ordinary quantity of fluid may suffice to keep them permanently open. A cleft spine will thus be produced without the watery tumour; but the openness of the spine will generally in cases of this kind lead to the secretion of an unnatural quantity of the spinal fluid; for it seems a general law that, other things being equal, the quantity of fluid secreted in each part is inversely proportionate to the resistance offered by the walls of the cavity into which it is poured.

Spina bifida is almost always characterised by a tumour situated over the defective vertebræ, globular, elastic, and fluctuating, often attached by a narrowed base, and varying in size according to the extent of the fissure in the spinal canal. It is usually covered by healthy skin, and consists of the dura mater, and one or more of the other membranes of the spinal cord, protruded in a sac through the space between the separated arches, and filled by a clear serous fluid. On pressing such a tumour the patient may become insensible, or be convulsed; for the fluid within it communicating with that within or around the brain and spinal chord, the pressure made upon it is felt with equal force by the whole of those organs. The parts of the body below the tumour are often paralytic, not from the pressure of the fluid, for that is equally diffused, but from disease of the cord coincident with that of the arches.

Spina bifida is most common in the lumbar and sacral regions, in which the vertebral arches are latest completed: it is most rare in the neck, and is there also most dangerous, because of the great number of nerves which, by the coincident disease of the spinal cord, may be paralysed. It does not commonly interfere with the general health: but by the friction to which, when the tumours are large, the skin is subjected, and by the distension produced by the increasing secretion of fluid, the sac is liable to inflame and ulcerate, till, exposing the spinal cord, or its membranes, death is produced by their inflammation; or, the quantity of fluid secreted may be so great as to produce death by its pressure on the cord and brain, in a manner similar to that in which hydrocephalus often terminates.

In one of these modes, spina bifida, when accompanied by excessive secretion, almost always terminates fatally, though patients may survive with it for ten or even twenty years. Life may generally be prolonged by maintaining a gentle even pressure upon the tumour, so as to supply the necessary resistance to the effusion of more fluid. In a few cases a repeated evacuation of the fluid, and then firm pressure upon the sac, has been found successful; and lately, M. Tavignot has related some cases which he cured by slicing off the tumour, and instantly bringing together the edges of the mouth of the sac, and so holding them till they had united and formed a firm cicatrix.

That just described is by far the most common form of spina bifida; others more rare are those in which not the arches only, but the bodies of the vertebræ also are cleft, the two lateral portions in which each is developed being kept apart, so that a portion of the spinal canal is open in front towards the cavity of the abdomen. Some differences of character also depend on the seat of the fluid secreted: it is generally in the sac of the arachnoid, but sometimes is in the tissue of the pia mater, or in both it and the sac, or, yet more rarely, in the central canal of the spinal cord.

SPINA VENTO'SA is a term now obsolete, which was applied by old surgeons to abscesses in bone, accompanied with excessive swelling, and then to nearly all the diseases indiscriminately in which either bones or joints become enlarged.

SPINACH. One of the species of this genus, the *S. oleracea*, the common spinach, is well known on account of its use in the kitchen. It has an herbaceous stem one or two feet high, branched, and hollow; arrow-shaped leaves; male flowers in long spikes, abounding with pollen; female flowers on another plant, axillary, herbaceous, and small. The fruit is a small round nut, which is sometimes very prickly.

There are two principal varieties cultivated in gardens, the prickly-fruited, with triangular, oblong, or sagittate leaves, and the smooth-fruited, with round or blunt leaves. The former is considered the hardiest, and is therefore employed for winter culture; the latter is used for summer crops. Of these varieties there are several sub-varieties, varying in the size, thickness, and shape of their leaves.

For the winter crop the seed is sown at the beginning of August. A light, dry, rich soil should be preferred, and, if possible, in a sheltered situation. When the plants have put forth two pair of leaves, the ground should be hoed and the plants thinned. By October or November the outer leaves of the spinach are fit for use. In February, when fine weather occurs, the plants should be again attended to, cleaned, and thinned out, and in this way it may be made productive till April or May, by which time the summer sort will be ready. The first sowing of the round-leaved spinach or smooth-fruited should take place at the end of January in some sheltered border. This crop should be successively thinned out till the plants are eight or ten inches apart. Successive sowings may be made, in order to ensure a constant supply in February, March, and April, and, if desirable, these sowings may take place between rows of cabbages, &c.

Spinach is often sown in narrow drills, which is rather more troublesome at first, but this is made up for by the facility with which clearing, thinning, and gathering are afterwards accomplished.

For preserving seed, those plants which are of the most stocky growth should be selected. The winter crops run up soonest, but seed may be obtained from spring crops in July and August. The new seed is the best for sowing, although it will keep very well for a year. When the plants are saved for seed, the male plants, which are easily distinguished by their flowers, may after fertilisation be drawn and thrown away.

Spinach is sometimes grown by the farmer for the purpose of obtaining a crop of seed for the uses of the gardener. In the selection of land for this purpose, care should be taken that it is finely prepared by ploughing and harrowing in the early spring, and some well-rotted dung should be ploughed in where the soil is not of the best quality. When the spinach has blossomed, the male plants should be drawn out, which serve at this time as excellent food for pigs, and might be given to other animals with advantage. There is much uncertainty about this kind of crop; sometimes, however, it turns out very advantageous.

SPINAL IRRITATION. This term has been applied to those functional disorders of the spinal cord and its nerves, which do not readily fall under the definitions of diseases of the same organs having more precise symptoms. Under the heads TETANUS, CHOREA, HYSTERIA, NEURALGIA, HYDROPHOBIA, and PARALYSIS, will be found descriptions of definite derangements of the spinal cord and its nerves. But there is a general state of the nervous system in which some of the symptoms of one or all of these diseases may occasionally be present, and in which there is very commonly present, pain in the spinal column induced or increased by pressure or percussion. To this state the term "spinal irritation" has been applied. What the precise condition of the nervous system is in this disease it is impossible to say, but the general theory of its nature is that the spinal cord at some one or more points is congested, and that this congestion acts upon the sensitive or motor nerves proceeding from this part of the cord, and gives rise to the pains, spasms, and other anomalous symptoms complained of by the patient. This condition is not unfrequently referred to hysteria, but as it may come on in the male as well as the female, there is evidently an impropriety in the use of this term.

It would be quite impossible to describe here all the nervous symptoms that may be referred to spinal irritation. Wherever nerves of motion and sensation are distributed they may become disordered, and thus there is no organ or part of the body that may not be the seat of excessive pain or paralysis of sensation, of spasmodic or convulsive action, and of a paralysis of motion. Such symptoms when they are not fixed, and are connected with pain on pressure of the spinal cord, are said to depend on spinal irritation. Whether these symptoms depend on a morbid condition of the spinal cord, or of the muscular or nervous tissue, or of the blood, are still questions admitting of discussion.

The treatment of these cases has been directed very much by the theory held with regard to the cause of the nervous symptoms. Those who advocate the theory of congestion of certain portions of the cord, recommend the employment of counter-irritants over the tender part of the spine, whilst those who believe that they arise from an under nutrition of the nervous and muscular tissues, recommend a treatment addressed to the restoration of the nutritionary powers of the system. Those who think the blood is the source of the disorder, likewise adopt the same general principles of treatment.

Whatever may be the theoretical views held with regard to the nature of the symptoms, known under the name of spinal irritation, there seems to be a general agreement that they come on in asthenic states of the system, and that antiphlogistic measures must not be had recourse to without great caution.

Relief from pressing occupations, a nutritious diet, change of air, cold bathing, the preparations of iron and quinine, are the great means that must be looked to for the cure of the disordered states of the nervous system. When the painful symptoms arise from over-exertion of the muscles, as is often the case, artificial support may be given with advantage to the particular muscles. Friction over the seat of pain, and the application of stimulants, as turpentine, ammonia, and brandy, in the form of embrocation with oil or glycerine, has been found very beneficial. Where the pain is very acute, or the muscular action excessive, sedatives, as opium, henbane, and belladonna, may be given internally and applied externally.

(Laycock *On the Nervous Diseases of Women;* Bennett, *The Principles and Practice of Medicine;* Inman, *The Phenomena of Spinal Irritation.*)

SPINET, a musical instrument of the harpsichord kind, but differing in shape and power, formerly much in use, though now entirely superseded by the piano-forte. The *Spinet* had but one string to each note, which was struck by a quilled jack, the latter acted on in the usual manner by a key. The tone was, of course, comparatively weak, but pleasing, and as the instrument was small in dimensions and cheap in price, it answered the purpose of those who did not find it convenient to purchase a harpsichord. The outline of its ordinary form was nearly that of a harp laid horizontally, supposing the clavier, or key-board, to be placed on the outside of the trunk, or sounding part, of the last-named instrument.

SPINNING. There are two entirely distinct manufacturing operations to which this name is given—the one relating to animal and vegetable fibres, and the other to certain soft metals.

Fibre Spinning.—This kind of spinning consists in forming a flexible cylinder of greater or less diameter, and of indeterminate length, out of vegetable or animal fibres, arranged as equally as possible alongside and at the ends of each other, so that, when twisted together, they may form an uniform continuous thread. The primitive modes of spinning by the spindle and distaff, and by the spinning-wheel, which are still extensively practised in the East, and not entirely superseded in some remote districts of Scotland, only enable the spinner to produce a single thread; but with the almost automatic spinning-machinery which has been called into existence by the cotton manufacture, one individual may produce nearly two thousand threads at the same time. The history of the series of inventions by which this result has been gradually attained has been already given under COTTON MANUFACTURE; together with wood-cuts and descriptions of some of the chief machines. The spinning of flax, silk, and wool partake of the same general character as that of cotton; so far as they differ they will be found noticed under LINEN MANUFACTURE; SILK MANUFACTURE; and WOOLLEN AND WORSTED MANUFACTURE.

Metal Spinning.—This is a peculiar branch of Birmingham and Sheffield manufacture, in which articles of use and ornament are produced without forging, casting, stamping, or cutting, by bringing into play the ductility of the metal. The metal employed is chiefly one or other of the soft mixed white metals, such as Britannia metal. Teapots, and such-like articles, are shaped in this metal almost entirely by the process of spinning. There is first prepared a wooden mould, of the exact size and shape; and this mould is fixed upon a lathe. Then a circular piece of the thin sheet metal is taken and fixed temporarily in contact with the bottom or flat surface of the lathe. Burnishers and smooth tools are then pressed cautiously against the metal, while the mould is rotating, and made to conform to all its curvatures—stretching out a little to cover the convexities, and compressing a little to cover the concavities. The ductility of the metal alone enables it to do this; the bending takes place gradually, so as to enable the particles of the metal to accommodate themselves to their altered position. Teapots, plated candlesticks, dish-covers, bell mouths of musical instruments, &c., are made by a succession of processes of which this is the chief; and a large quantity of cheap Birmingham jewellery is worked into form in a similar way.

SPIRAL, a name belonging properly to curves which wind round a point in successive convolutions. The easiest mode of representing such curves algebraically is by means of polar COORDINATES: hence, in many of the older English works, any curve referred to such coordinates is said to be considered as a spiral. Thus we have the circle considered as a spiral; the ellipse considered as a spiral, and so on. The rest of this article is intended only for those who have some knowledge of the mathematical part of the subject.

If r be the radius vector of a curve, θ the angle which it makes with a given line, and $r=\phi(\theta)$ the equation of the curve, it is obvious that if $\phi\theta$ be a common trigonometrical function of $\sin\theta$, $\cos\theta$, &c., the curve will not have an unlimited number of convolutions. The whole of the curve from $\theta=2\pi$ to $\theta=4\pi$, will be merely a repetition of that from $\theta=0$ to $\theta=2\pi$. Thus, $r=\sin\theta$ is the equation of a circle of a unit diameter, tangent at the origin to the line from which r sets out; the fifteenth half-revolution of the radius vector is only the fifteenth description of this circle. It is then only when the angle θ occurs independently of trigonometrical quantities, that any curve is represented which can properly be called a spiral. Thus, the spiral of Archimedes, or Conon, of which the equation is $r=a\theta$, has a convolution in which r changes from 0 to $2\pi a$, while θ changes from 0 to 2π; another, in which r changes from $2\pi a$ to $4\pi a$, while θ changes from 2π to 4π, and so on. The principal spirals to which distinct names have been given, are—

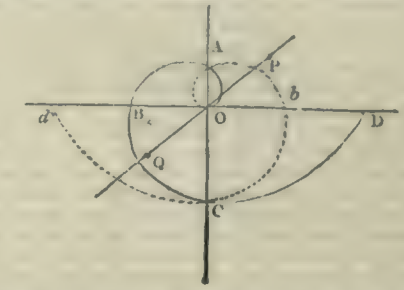
	Equation.
1. Spiral of Archimedes . . .	$r=a\theta$
2. Reciprocal Spiral	$r\theta=a$
3. Lituus	$r^2\theta=a$
4. Logarithmic or Equiangular Spiral	$r=ab^\theta$

with some others of less note. The figures of these spirals are given in all books on the application of algebra to geometry.

It has hitherto been universal to consider spirals in a manner which has deprived these curves of half their convolutions; this has been done by refusing to entertain negative values of the radius. For example, in the spiral of Archimedes $r=a\theta$, a being a positive quantity, the curve is supposed to have no convolutions when θ is negative, or when the radius revolves negatively. The consequence is, that the curve begins abruptly at the origin. It would be a matter of little importance to insist on the existence of the additional branches which belong to the negative radii, if it were not that the other mode of representing curves, by means of rectangular coordinates, always gives the additional branches: so that, if we refuse to receive the latter as coming from the polar equation, we have only the alternative of supposing that the mere transformation of coordinates destroys a part of the curve. In the spiral of Archimedes, for example, the rectangular and polar equations are—

$$y = x \tan \frac{\sqrt{(x^2+y^2)}}{a}, \qquad r = a\theta.$$

The first, treated in the usual way, gives a curve of which there is



one succession of convolutions beginning with O A B C D, and another beginning with O A b C d. But the second equation, which is only the first in a different form, does not yield any of the second set of convolutions, unless by means of the negative values of the radius vector answering to negative values of θ.

The manner in which the negative value of r is to be treated, is as follows:—Every line passing through the origin, as P O Q, makes two angles with the positive side of the axis of x, P O D, less than a right angle in the diagram, and Q O D, between two and three right angles: the second of which may be considered as the common angle Q O D, taken negatively. The bounding directions of these angles are different, O P and O Q: the rule is, whichever angle the straight line Q O P is supposed to make with O D, let the bounding direction of that angle be the positive direction, and the other direction negative. Thus, when P O D is the angle, O P is positive and O Q negative: when Q O D is the angle, O Q is positive and O P negative. In this manner it will be found that the first three of the four spirals above enumerated have never been completely drawn. There is little need to insist much on the necessity of the extension here described: one more instance may suffice. Let the reader trace the curve whose equation is—

$$2y^2 = 1 - 4x - 2x^2 \pm \sqrt{1-8x},$$

derived from $r=1-2\cos\theta$. The rectangular equation gives a curve of two loops, of which the polar equation will only yield one, unless negative values of r be employed, in the manner above described. Nevertheless, if the process had been inverted, and the polar equation deduced from the rectangular, we should have found $r=\pm 1-2\cos\theta$ for the former; and the effect of the double sign is that the positive values of r only, in the two equations $r=1-2\cos\theta$, and $r=-1-2\cos\theta$, will give the complete curve deduced from the rectangular equation. As far as this instance goes, it might seem as if the complete polar equation, as reduced from the rectangular, would give the whole curve by means of positive radii; though at the same time a single instance hardly proves anything. But even granting that the passage from the rectangular to the polar equation will always give forms enough to the latter to trace the whole curve from positive radii, it remains indisputable that the other transition, from the polar to the rectangular, requires the negative radii to be taken into account.

SPIRAL OF ARCHIMEDES. [SPIRAL.]

SPIRE (in German, *Spitze,* or *Thurm-spitze;* in French, *Flèche*), in Gothic architecture, is used to designate the tapering pyramidal mass erected on a tower by way of finish and ornament. The origin of the spire, like that of the pointed arch, is merely matter of conjecture. The probability is that it arose out of the peaked roof usually given to campaniles and towers of a preceding period, which form was afterwards gradually improved upon and refined, till it eventually grew up into the slender tapering spire. The tower of Than church, Normandy, engraved under NORMAN ARCHITECTURE, may be referred to as an example exhibiting the rudiments of the spire, it being no more than a steep peaked roof or low pyramid, whose height does not exceed three-fourths of its base. A *peak* of this kind differs also from the spire both in being the same in plan as the tower on which it is placed, and in being immediately set upon it, whereas the spire is almost invariably an octagon or other polygon, and is surrounded at its base with a parapet. In Italy, where campaniles are usually detached square towers of very slender or lofty proportions, the spire is almost unknown, for such towers have seldom more than a mere pyramidal roof or peak. There are some few instances of square spires; among them a very singular one at Egeln in Germany, where two such spires are set immediately together upon the same tower. But however slender in their proportions such spires may otherwise be, they have a certain heavy massiveness of form. When therefore greater loftiness and lightness were aimed at in this feature, the adoption of a polygonal plan for it became almost matter of course; for although in a geometrical drawing the general outline and proportions of a spire are the same whether it be square or octangular in plan, the perspective or actual appearance is widely different; because in the latter case the diagonal breadth of the square tower below is cut off, and each side or plane of which the spire is composed becomes a much more pointed triangle. Besides which, the polygonal spire produces a degree of contrast and variety highly favourable to general effect in the Pointed style.

A gradual and progressive transition from the mere peak or pyramidal roof to the slender tapering spire, cannot, however, be clearly traced. On the contrary, some of the earliest deviations from the simple pyramidal form appear to have produced uncouthness rather than lightness; for although much greater loftiness upon the whole was so occasioned, the appearance of it was reduced by the sides of the tower being made to terminate in gables cutting into, and therefore partly cutting off, the base of the pyramid or spire itself. Many of the earlier German edifices contain examples of this peculiarity—one almost confined to them; among others the cathedrals of Worms and Gelnhausen, the church at Andernach, and that of the Apostles at Cologne, exhibit many varieties of spires, or rather *spire-roofs*, springing up from gables at their base: and in some the gables are so large, and rise up so high, that the appearance of spire is almost entirely lost. Such is the case with the pyramidal covering of the square tower at the west end of the church at Gelnhausen, of which the portion above the gable forms a mere capping. In this country the spires in the First Pointed, or Early English style, were usually much less acute than in those of the Second Pointed period, when this feature arrived at its greatest perfection both in design and decoration. The outline of spires of this Second Pointed period is commonly very graceful and refined, a well-considered entasis being often given: the spires of Salisbury Cathedral and St. Mary's Church, Oxford, are well known and admirable examples of this period.

Spires vary much in character. In this country a spire set immediately upon a tower without any parapet, &c., at its base, is technically described by the term *broach*. There are indeed so many peculiarities in spires, that it is highly desirable to have descriptive terms for them. First, as regards its base, a spire may be said to be *cluster-based* when surrounded below with pinnacles connected with it, and from among which it seems to spring up; of which kind St. Mary's, Oxford, is a celebrated example. The Hôtel-de-Ville, at Ypres, has a spire clustered with four exceedingly tall pinnacles or lesser spires. Where there are windows placed *against* a spire, rising *upright* like the dormers or lucarnes on a roof, the term *Lucarned* would express that character; we have therefore not scrupled to make use of it in the annexed table of spires, where it is applied, among others, to those of Lichfield cathedral, which have several tiers of such windows, and are described accordingly. Where the height does not exceed two diameters of its base a spire might not inconveniently be termed a *stump-spire*. *Crocketed* and *banded* are terms requiring no explanation; but in regard to the first it may be remarked, that spires, otherwise quite plain, are sometimes ornamented with *crockets* along their edges; and with respect to *bands*, they are sometimes little more than string-mouldings, but in other cases broad and enriched surfaces. Many of the spires in Normandy are ornamented with such a number of bands, that they form alternating courses with the plain spaces between them. *Finialled* is a term which does not apply to any of our English spires; but that of St. Stephen's, Vienna, and some other continental spires, have an exceedingly large and rich finial, which ornament gives them a particular boldness of expression. The *Tabernacle-spire* also is one of which there is no example in this country, but of which the one just mentioned, and those of Strasburg, Ulm (as designed), Thann in Alsace, and many others, are specimens, the tower and spire being carried up from the ground in a succession of diminishing stages, all profusely adorned with pannelling, niches, canopies, pinnacles, and other tabernacle-work, in such a manner that it is barely possible to distinguish where the upright portion or tower terminates, and the spire itself begins, the latter seeming little more than the uppermost stage in continuation of the rest. Neither have we any instances of *Open-work* spires, or of such as, if not actually perforated, are yet entirely covered with tracery. That at Freyburg, and those at Burgos and Batalha, are exceedingly rich specimens of the kind. The chapter-house of Burgos also has a series of very large pinnacles or small spires of tabernacle character. Cambrai and Esslingen on the Neckar afford other examples of open-work spires.

There are various other circumstances which, though they do not affect the spire itself, produce greater or less difference in regard to the character of the structure of which it is a component feature. Very much, for instance, depends upon its situation in the general plan: at

TABLE OF SPIRES, ENGLISH AND FOREIGN.

	Tower.	Spire.	Total Height.	Remarks.
	Feet.	Feet.	Feet.	
Old St. Paul's . . .	260	274	534	Six diameters high.
Salisbury	207	197	404	Date about 1350. Three enriched bands. Nearly 5 diameters.
Norwich	140	163	303	Plain, rather more than 5 diameters high.
Lichfield	114	138	252	Lucarned, 5 tiers of windows. Nearly 5 diameters high.
,, two western .	89	103	192	Lucarned, 4 tiers; 4½ diameters high.
Chichester	..	..	270	Pinnacled and lucarned below; banded with two broad rich bands; else quite plain. Both tower and spire fell, Feb. 21, 1861.
Oxford Cathedral . .	94	52	146	Date about 1220.
Oxford, St. Mary's . .	86	94	180	Spire itself quite plain, lucarned with a canopied window below, on four sides. Embased by very rich canopied niches and pinnacles.
Louth	148	140	288	Embased with lofty pinnacles and flying buttresses. Crocketed. 6 diameters.
Grantham (about) . .	140	..	250	Lucarned, crocketed, large crocketed pinnacles at base. Base of spire less than tower.
Bloxham	101	94	195	A very beautiful example. Spire 5 diameters high. Date about 1350.
St. Michael's, Coventry .	136	164	300	This tower and spire a very fine example.
St. Mary's, Stamford .	..	..	..	Date about 1260. Base without parapet or pinnacles. Lucarned, 4 tiers. Spire 2½ diameters.
Cologne (as designed) . .	330	200	530	Two west spires enriched with tracery, and crowned by large finials.
Strasburg . . .	364	110	474	Two west towers, only north-west spire.
St. Stephen's, Vienna . .	285	180	465	On south side of church. Example of a tabernacle tower and spire.
Ulm (as designed) . .	320	171	491	Tabernacle example. Tower and spire in centre of west front.
Freyburg	221	159	380	Rich open-work spire. Tower and spire in centre of west front.
Marburg	184	88	272	Two west towers and spires. Base of spire gabled. Spire 4½ diameters.
Nürnberg, St. Laurence .	180	90	270	Two west towers and spires. Base of spire gabled. Spire 4½ diameters.
Nürnberg, St. Sebaldus .	170	90	260	Two west towers and spires. Base of spire gabled. Spire 4½ diameters.
Antwerp	..	..	366	Two west towers, only north-west spire.
Chartres "New Spire" .	..	..	371	Two west spires, the north-west, or "New," spire loftier and more enriched than the other.
Bayeux	142	104	246	Two west spires. The north-west spire has 6 broad bands; the other plain. Diameter at base 27 feet.
Caen, St. Stephen's . .	155	107	262	Lucarned at base and banded.
Caen, St. Peter's . .	134	110	244	Base of spire 24 feet. Spire has 9 bands, with small hexafoil, quatrefoil, and trefoil apertures between them. Crocketed.
Batalha	113	57	170	Very rich open-work spire. Diameter at base 19 feet.
Burgos Cathedral . .	..	..	280	Two short or stump but very rich open-work spires, at west end. Date of spires 1442.
Glasgow	115	105	220	Lucarned, banded, lower band richly moulded and quatrefoiled, and surmounted by fleurons. Diameter at base 27 feet.

Salisbury and Norwich, the spire is raised upon a tower at the intersection of the cross, or in the centre of the plan; whereas in most continental cathedrals and large churches there are two spires on the towers of the west front, though in some instances (Strasburg, Antwerp) only one has been erected. Several, however, have a single tower and spire in the centre of the west front (Ulm, Freyburg, Thann in Alsace), in which case the tower itself begins to diminish almost from the ground, and the whole becomes what we have described as of the *tabernacle* character. In most of our English churches (not cathedrals) the spire is placed upon a tower at the west end, as at Grantham, Louth, Bloxham, &c. If we except Peterborough, where they are very diminutive, the only English cathedral which has two western spires is Lichfield, which is further remarkable as having a central tower and spire also. Besides the richness and variety thus produced, the larger central spire serves to balance the whole composition, whereas else the body of the structure is apt to look low in comparison with the west end. At St. Stephen's, Vienna, the tower and spire are singularly placed on the south side of the edifice, it having been intended to balance them by a corresponding tower on the north side. At Gelnhausen, on the contrary, there is a group of spires at the east end.

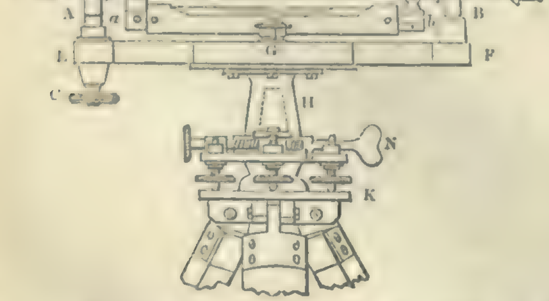
Though so much depends upon the proportion of spires to their own diameters and to the height of the towers, almost the only thing that is specified in the usual description of spires is the entire altitude from the ground, which single measurement, unaccompanied by others, gives no idea of the relative dimensions of the spire or how it is proportioned. Some of the loftiest spires, as they are popularly termed, are by no means lofty, being not above a third of the entire height, and not more than four of their own diameters. The spire of Strasburg, for instance, is only 110 feet out of 474, or less than one-third of the tower itself. At Antwerp again the spire is a mere *peak* crowning the uppermost stage of the tower, while the tower itself is twice as high as the roof of the church. If we compare Salisbury with Norwich, the spire of the latter cathedral will be found, though of less dimensions, much loftier in relation to the rest than the other, being in the ratio of 163 to 308 feet, while Salisbury is only 197 to 404. We have, therefore, drawn up a short table of spires (see preceding page) showing, where we can, the separate as well as united heights of the respective towers and spires.

SPIREIN. ($C_{42}H_{24}O_{20}$?) The yellow colouring matter of the meadow-sweet (*Spiræa ulmaria*). It is a crystalline yellow powder insoluble in water, but very soluble in alcohol and ether. The dilute solution is yellow, but becomes dark green on concentration. It possesses a slight acid reaction, and cannot be volatilised without decomposition.

SPIRIN. [SALICYLIC GROUP.]

SPIRIT, a term used in chemistry. When employed alone, it is now almost exclusively applied to spirit of wine, or alcohol; formerly however the name spirit was given to most substances capable of being vaporised and condensed by distillation, and to some not obtained by distillation. It will be requisite merely to name a few of those compounds to show how extensively it was used in naming substances of very different origin and composition: thus nitric acid was called spirit of nitre: hydrochloric acid, spirit of salt; sulphuric acid, spirit of sulphur; chloride of tin, spirit of Libavius; solution of ammonia, spirit of sal-ammoniac, or sometimes spirit of hartshorn.

SPIRIT-LEVEL, a tube of glass nearly filled with spirit of wine or distilled water, and hermetically sealed at both ends, so that when held with its axis in a horizontal position, the air which occupies a part not filled with the spirit or water places itself contiguously to the upper surface. The tube being supposed to be perfectly cylindrical, the exact horizontality of its axis is ascertained by the extremities of the air-bubble being at equal distances from the middle point in the length of the glass.



The spirit-tube is used in determining the relative heights of ground at two or more stations, and in order to render it available for this purpose, it is placed within a brass case having a long opening on the side which is to be uppermost, and is attached to a telescope; the telescope and tube are then fitted to a frame, or cradle, of brass, which is supported on three legs. In the interior of the telescope, at the common focus of the object glass and eye-glasses, are fixed, generally, two wires, at right angles to each other, their intersection being in the line of collimation, or that which joins the centres of all the lenses.

The case containing the spirit-tube is made to turn on a joint at one extremity, as *a*, by the revolutions of a screw, *b*, at the opposite extremity; and the telescope rests, near each end, within two arms at the top of a small pillar, A or B, the pillar and its arms resembling the letter Y, and the interior sides of the arms being tangents to the tube of the telescope. One of these pillars is made capable of a small movement in a vertical direction by turning a screw, C, at its base, for the purpose of elevating or depressing one end of the telescope and spirit-tube; and in the more perfectly constructed instruments, both the pillars may be so moved. The pillars are at the extremities of a strong brass plate, E F, the under side of which is connected with the tripod-stand, which supports the whole instrument; and a compass-box, G, is attached immediately to the plate, as in the figure, or is raised above the telescope by means of four small pillars. A hollow conical socket, H, of brass is screwed to the under side of the plate, and is intended to receive a piece of bell-metal of a corresponding form, which constitutes the upper part of the stand. This piece serves as a vertical axis, upon which the telescope, the spirit-level, and the compass are to turn round horizontally: sometimes, however, the conical pivot projects from the under part of the plate, E F, and the socket is on the stand.

The three legs which are to support the instrument are firmly fixed to a circular plate, K, perforated at its centre, and having about the perforation a hollow spherical zone, resembling a small inverted cup. In the simpler kinds of spirit-levels a circular plate, L, of the same dimensions as the last, carries above it the pivot before mentioned; and from below it projects a stem, terminating in a ball, which fits the inverted cup or socket. By means of four screws which pass through one of these two plates (the upper plate in the cut), nearly at the extremities of two diameters at right angles to one another, the upper plate is made parallel to the horizon, and consequently the conical pivot which it carries is brought to a vertical position.

The above is a general description, which will serve nearly for every spirit-level at present in use, whatever be its form; and the following is the usual manner of performing the adjustments, preparatory to the instrument being employed on the ground:—

The telescope should, by a proper opening of the legs of the stand, be at first rendered as nearly level as can be estimated by the eye; then, being turned so as to lie vertically above the line joining two opposite screws in what are called the parallel plates (K and L), the spirit-tube is brought to horizontal position by relaxing the screw nearest to its higher end, and tightening that which is opposite to it: the like operation is to be performed with the other pair of screws, after placing the telescope vertically above them. In order to render the spirit-tube parallel to the axis of the telescope, after the bubble of air has been made to occupy the middle place by the process just mentioned, let the telescope be reversed in the arms (the Ys as they are called); then if the bubble does not still occupy the middle, it must be made to do so by successive trials, endeavouring to correct half the error by means of the screw *b*, and the other half by the screw C.

The eye-piece of the telescope must be moved inwards or outwards till the wires in the field of view are distinctly seen; and the object-glass must also be moved by means of the pinion, M, till the station-staff, placed at any convenient distance (suppose 100 yards), is also distinctly seen. By a few trials, the distance between the eye and the object-glass may be made such that the intersection of the wires will appear to remain constantly at one point on the staff while the observer in looking through the telescope varies the position of his eye. It is necessary besides that the intersection of the wires should be precisely in the line of collimation, or the optical axis of the telescope: for this purpose the point of intersection should be directed to some well-defined mark at a considerable distance. The telescope must then be turned on its axis; and if the intersection remains constantly on the mark, that adjustment is complete; otherwise it must be rendered so by means of the screws, *c d*, &c., on the telescope; those screws being placed at the extremities of two diameters at right angles to one another, on being turned they move the plate carrying the wires in the directions of those diameters. In order that the correction may be made, the apparent displacement of one of the wires, in consequence of the telescope being turned half round on its axis, should be observed, and the screws turned till half the displacement is corrected; the like observation and correction may then be made for the other wire: a few repetitions of each adjustment will probably be necessary before the error is wholly removed.

The level constructed by the late Mr. Troughton differs from that which has been above described in having the spirit-tube sunk partly in the telescope; and the latter, being incapable of a movement about its axis, does not admit of a separate adjustment for the intersection of the wires.

Mr. Gravat, who made considerable improvements in the mechanism of these instruments, recommends the following method by which the error in the positions of the cross-wires and spirit-tube may be ascertained and corrected:—Let three pickets be driven into the ground in a line and at equal distances from one another, and let the spirit-level be set up successively in the middle between the first and second, and between the second and third pickets; then, having by the screws of the instrument adjusted the spirit-tube so that the bubble of air may retain the same place while the telescope is turned round on the vertical axis, direct the object-end of the telescope successively to the station-staves held up on the different pickets, read the several heights, and take the differences between those on the first and second, and on the second and third staff. Now the staves being at equal distances from the instrument, it is obvious that any error which may have existed in the line of collimation, or from the spirit-tube not being parallel to that line, will be destroyed, and the differences between the readings on the staves are the differences in the levels of the heads of the pickets; but unless the adjustments are perfect, this will not be the case if the instrument be set up at any point which is unequally distant from all the pickets; therefore from such point direct the telescope to the staves, and take the differences of the readings as before. On comparing these differences with the former, a want of agreement will prove that the intersection of the wires is not in the optical axis: and the error may be corrected by means of the screws belonging to the wire plate. After the agreement has been obtained, should the bubble of air not stand in the middle of the tube, it may be brought to that position by the screw *b*, at one extremity of the case, and the instrument is then completely adjusted. (Simms, 'Treatise on Mathematical Instruments.')

The spirit-level is usually provided with a clamp, N, and a screw, P, by which when the axis of the telescope has by hand been brought near the object, the coincidence may be accurately made by a slow and steady motion about the vertical axis.

The spirit-tube or level which is employed for the adjustment of transit telescopes or astronomical circles is contained in a case with feet or with loops at its extremities, in order that it may either rest above or be suspended below the horizontal axis of the instrument to be levelled; also the upper part of the case is furnished with a graduated scale, the divisions of which are numbered on each side of a zero point, this point being usually placed near each of the two extremities of the air-bubble when the tube is in a horizontal position. Having set up or suspended the spirit-tube, the two particular graduations at which the extremities of the air-bubble rest are marked; and half the sum, or half the difference of these numbers, according as the extremities of the bubble are in the same or in opposite directions from the two zero-points, being taken, gives the distance of the centre of the bubble from the middle between those points. The level being then reversed, the graduations at which the air-bubble rests are again marked, and half the sum or half the difference is taken as before. A mean of the two distances thus found is the true distance of the centre of the bubble from the middle point on the scale; and the screw which elevates or depresses one end of the axis of the telescope being then turned, till either extremity of the bubble has moved, in a direction contrary to that in which the centre of the bubble had moved from the middle of the scale, through a number of divisions equal to that mean distance, that axis will be brought to a horizontal position. This method is used in preference to that of successive trials, in order to avoid the trouble of making several reversions of the whole instrument.

The levelling-staff till lately in general use for finding the relative heights of ground is a rod consisting of two parts, each six feet long, which, by being made to slide on one another, will indicate differences of level nearly as great as twelve feet. The face of the rod is divided into feet, inches, and tenths, or into feet with centesimal subdivisions; and a vane, or cross-piece of wood, perforated through the middle, is moved up or down upon the rod by an assistant till a chamfered edge at the perforation is seen by the observer at the spirit-level to coincide with the horizontal wire in the telescope. The height from the ground to the chamfered edge of the vane must be read by the assistant; and it being out of the power of the observer to detect any mistake in the reading, it becomes very desirable that the graduations on the rod should be sufficiently distinct to allow the heights to be read at the spirit-level itself. The rod proposed by Mr. Gravat for this purpose is divided into hundredths of a foot by stripes which are alternately black and white, and are numbered at every foot in the usual way with figures great enough to be seen on looking through the telescope; the tenths of a foot are indicated by lines longer than the others. A similar staff has been proposed by Mr. Sopwith and Mr. W. P. Barlow; and the former gentleman, besides the number of every foot, has given a number to every first, third, fifth, and ninth decimal. Mr. Barlow's rod is also divided into centesimals of a foot; but the marks, instead of being stripes whose edges are parallel to one another, have the form of triangles: each tenth mark, however, is in the form of a lozenge, or double triangle, for the sake of greater distinctness.

SPIROUS ACID. Synonymous with hydride of salicyl. [Salicylic Group.]

SPLEEN, DISEASES OF THE. These do not appear to have been much studied in this country, because they do not very frequently occur; they are, however, by no means of unusual occurrence in moist climates, whether warm or temperate, as Italy, Holland, South America, and some parts of India; in fact, wherever malaria exists. The spleen is liable to many sorts of disease: Dr. Bigsby ('Cyclop. of Pract. Med.') enumerates as many as ten, but of these only the most important can be here noticed. Splenitis, or inflammation of the spleen, may be either acute or chronic; though Dr. Baillie remarks that this organ is much less subject to inflammation than many other of the abdominal viscera. ('Posthumous Lectures and Observations on Medicine,' 1825, unpublished.) Acute inflammation of the spleen, together with heat, fulness, and tenderness in the splenic region, with pain upon pressure, is accompanied with the usual pyrectic signs, and often with a pain extending over the whole of the abdomen, but particularly in the left side, and shooting from the diaphragm to the left shoulder. There is also not unfrequently a dry short cough, and sense of constriction in the præcordia, sickness, or nausea, and a discharge from the rectum of black or livid blood, from a rupture of some of the splenic vessels. Of this disease a remarkable instance, which terminated in nine days, has been recorded by Dr. Ley, in the 'Transactions of the College of Physicians of London' (vol. v. p. 304). The texture of the spleen after death was in this case so altered as to resemble an extremely soft piece of sponge, of which the cells had been filled with an intimate mixture of pus and grumous blood. On placing it in water, innumerable vessels, as fine as the fibres of swans' down, floated separately, rising from every point of the superficies of the organ. The contents of this spongy mass having been removed by repeated washings, something like an attempt at the formation of cavities to contain the matter manifested itself. No regular cyst however had been formed. All the other viscera, abdominal and thoracic, were healthy, except the uterus, whose inner surface was gangrenous. The common causes of inflammation of the spleen are much the same as those of inflammation of the liver, namely, suddenly suppressed perspiration, especially from currents of cold and damp air, and excess of spirituous potation; sometimes, however, the cause is too obscure for detection. With respect to the treatment, the usual antiphlogistic remedies may be employed, but promptly and energetically. Dr. Baillie says, he is not aware that inflammation of the spleen would require a different treatment from that of other viscera.

If after a certain period the inflammation do not yield, it assumes the chronic form, in which the variation in the severity and duration of the complaint is very great. If it has accompanied ague, the symptoms may possibly not have been urgent in the outset, but it is almost always a painful as well as formidable disease. It commonly lasts for some months, and may continue for years with remissions. With respect to the terminations of chronic splenitis, resolution does not take place often; suppuration is also rare upon the whole, and Dr. Baillie says he "had never met with an abscess in the spleen in all the dead bodies which he had examined." When pus is formed, it is of the ordinary creamy kind, but is sometimes concrete; it varies in amount from a few ounces to many pounds. The matter may find its way into the stomach, colon, or peritoneal cavity; it may burst into the left side of the chest, or into the lungs, inducing symptoms of phthisis; or it may empty itself outwards through the abdominal walls. Ossification of the spleen after inflammation is rare, as is also gangrene; softening, induration, and hypertrophy, especially the last, are much more common. With respect to the treatment of chronic splenitis, perhaps the best plan that can be adopted is the combination of aperients with iron and sedatives; the good effects of mercury in this disease being now generally considered precarious, trivial, and at best temporary. Local applications, such as cupping, issues, setons, &c., are sometimes productive of great benefit.

Besides the inflammatory softening of the spleen, there is another of a character quite peculiar, and unattended by any of the characteristics of inflammation, wherein the structure of the spleen is more or less destroyed, and it is often reduced to a simple bag, containing a substance which varies from the state of clotted or grumous blood to that of tar. This was very frequent in the Walcheren fever, in which cases the spleen was usually found after death of great size, and generally a mere bag filled with a liquid like tar, and weighing from three to five pounds.

One of the most common diseases of the spleen is hypertrophy, the most usual causes of which are ague and remittent fever. It is therefore chiefly to be found where these are endemical, but it is not very uncommon in any part of Great Britain. The size which this organ sometimes attains is enormous, and it is surprising to find how long persons can carry about with them very enlarged spleens, and at last die of some other disease. Dr. Bigsby quotes from Lieutaud the case of a woman who had for seventeen years a spleen weighing thirty-two pounds; similar facts are to be found in Haller. Dr. Baillie mentions ('Posthumous Lectures') having met with cases where it was so large as to occupy nearly all the left side of the abdomen, extending from the diaphragm to the pelvis. When the enlargement is so considerable that the lower end of the spleen can be felt under the margin of the ribs upon the left side, there can be no doubt with respect to the disease. When the hypertrophy does not reach this extent, its most characteristic symptoms, are a sense of weight in the left side, with or without evident swelling; inability to lie with ease on the right side; debility, without corresponding emaciation; disordered stomach, irritable bowels, dry cough, and absence of fever. The spleen, when enlarged, is always felt to be harder than in a natural state, but pressure upon it with the hand seldom produces pain. An hypertrophy of the spleen is sometimes followed by ascites; but there will frequently be no dropsy of the abdomen, even where this organ has been for a long time much enlarged. When this form of disease has been connected with ague, it more frequently subsides than in any other case; and the quina, which has been prescribed to cure the latter affection, will probably be serviceable also to the former. "When the enlargement has taken place independently of this cause," says Dr. Baillie, "it hardly ever subsides of itself, or is materially diminished by medicine. According to my experience, mercury, administered both externally and internally, produces very seldom any good effect; I have seen, I think, more advantage from a seton inserted under the skin which covers the spleen. In some cases it has appeared to be diminished in size by this remedy, and to be rendered softer; but I do not recollect a single instance, except after ague, in which it has been reduced to nearly its natural size. Temperate living, abstaining from violent exercise, and keeping the bowels open, must be to a certain degree useful in retarding the progress of the disease." The remedy largely employed in India for the cure of chronic tumour of the spleen is a compound of garlic, aloes, and sulphate of iron. When emaciation and diarrhœa are present, the garlic and aloes are macerated in brandy; under other circumstances, in vinegar. The proportion of aloes is so regulated as to produce three evacuations daily; and the medicine also produces copious secretions from the kidneys. The *Decoctum Aloes Compositum* with the *Tinctura* or *Acetum Scillæ* would probably prove equally effectual. The moxa, and even the actual cautery, have been recommended for this disease; and emetic cataplasms of tobacco-leaves, renewed constantly so as to keep up frequent vomiting, have in some instances produced the happiest effects.

Atrophy of the spleen is by no means so common as hypertrophy; and though some instances are related by modern writers, yet their statements are so meagre and unsatisfactory, that no use can be made of them. It is sometimes found exceedingly small and even shrivelled when some other organ is much enlarged, where there have been great discharges of blood, in ascites, and in extensive chronic disease. This form of disease of the spleen obviously admits of no remedy.

Hydatids in the spleen are found now and then, but not very often; Dr. Baillie had never met with a single case of them. It is hardly possible to discover their existence during the life of the patient, nor, even if it were more easy, could the complaint receive any cure, or even amendment, from medicine. The disease arises quite unconsciously to the patient; the first intimation of its existence being debility, dyspepsia, and the uneasiness created by a slowly increasing tumour, which in its progress causes further derangement by compression and displacement of other organs, and becomes itself perceptible externally. It is only when the containing membrane, or some organ, becomes inflamed, that fever, pain, and their fatal consequences ensue. Hydatids may prove fatal by passing into the peritoneal cavity from ulceration of the containing sac, or by disturbing the circulation, or by irritating other viscera; or the patient may live very long with this complaint, and die eventually of another disease during the indolent continuance of this.

Melanosis and calculi of the spleen are noticed shortly by Dr. Bigsby, but the instances are too rare to require any particular remarks here.

Rupture of the spleen from some external violence occurs not unfrequently; but in the majority of cases the injury is so overwhelming that little is left for the medical practitioner to do. Free venesection and perfect rest have occasionally saved life; but in many instances the patient dies in a few hours. In these latter cases the symptoms are great shiverings, coldness of body, vomiting, and other signs of extreme collapse: when there is time and strength for reaction, there is considerable fever, with a remarkable heat of skin, and great pain in the left side or all over the abdomen; the stools and urine are not materially affected.

(Good's *Study of Med.*; Gregory's *Theory and Pract. of Med.*; Bigsby, in *Cyclop. of Pract. Med.*, from which works, with Dr. Baillie's (posthumous) *Lectures and Observ. on Med.*, great part of the pathological part of this article is taken.)

SPLINT is a piece of wood or other rigid substance which is used in surgery to maintain any part of the body in a fixed position, and especially for the purpose of holding steadily together the portions of a fractured bone. Splints vary almost infinitely in form and size, according to the part to which they have to be adapted, and the position in which it is to be held; the number and the arrangement of them in each case are equally subject to variation; nor can a surgeon have a better rule than that of following no general plan, but of determining in each case the apparatus best fitted for its peculiar exigencies. [FRACTURE.] The material of which they are commonly made is light wood; each splint consisting either of one piece cut nearly to the form and size of the limb, or of several pasted together with a strap of linen so as to be flexible in one direction. In some cases tin is a preferable material; in some stiff pasteboard. In many cases also it is very advantageous to adapt the splints exactly to all the irregularities of the limb; and as this cannot be done with wood or any unyielding material, it is usual to employ one which, being applied moist and soft, gradually hardens. Stiff pasteboard will sometimes be sufficient, especially for children; but a better material for general use is sole-leather or gutta percha, applied while quite pliant after having been well soaked in hot water, and then bandaged closely to the limb and allowed to dry. Another plan of this kind now much employed is to form a splint of linen and some glutinous material, such as starch, or a mixture of white of egg and flour, or of mucilage of gum-arabic and whiting, made as thick as bird-lime. In using these, the limb or other part should be thinly padded with soft lint; then strips of coarse linen soaked in the tenacious material should be laid on, one over the other, till on each side of the limb they form a layer about as thick as a common wooden splint. The whole should then be surrounded with a neatly-applied bandage soaked in starch. When dry, splints of this kind will so exactly fit the part to which they are applied, and be so rigid, that a patient may with safety execute the slighter natural movements of a limb within a fortnight after it has been fractured. All the further care of a simple case of fracture will generally consist in the occasional replacement of the starched bandage, and the adaptation of the splints, by cutting their edges, to the change of form which the limb may undergo as the swelling diminishes. Splints of this kind however must not be applied till all the inflammation immediately consequent on the fracture has ceased. See Druitt's 'Surgeon's Vade-mecum.'

SPONDEE (*spondeus*, *σπονδεῖος*) is a foot which consists of two long syllables (- -). The name is derived from *σπονδή*, a libation, as the metrical prayers on such an occasion were generally of a slow and solemn movement. To produce this solemnity the spondee is often used instead of a dactyl in the hexameter or pentameter: and in iambic, trochaic, or anapæstic metres, instead of an iambus, trochee, or anapæst. There is no metre which consists of spondees alone, and indeed such a metre would be very disagreeable, even if it were possible; but spondees produce a good effect when mixed with other feet. An hexameter verse which has a spondee in the fifth place, is called a spondaic verse.

SPONGIA, MEDICAL USES OF. The use of sponge by surgeons, in its natural state, to absorb fluids, needs no notice, but it is also employed by them under the name of sponge tent, when prepared in a particular manner. This consists in dipping the sponge in melted wax, and compressing it between iron plates till it hardens on cooling; it is then cut into cylindrical or other forms. The pieces are introduced into sinuses and other narrow canals, with the intention of dilating them by the expansion of the sponge, when the wax melts by the heat of the part. Sponge tents are however little used by modern surgeons.

According to the analysis of Hornemann, sponge consists of a substance similar to osmazome, animal mucus, fat oil, a substance soluble in water, a substance only soluble in potash, and traces of chloride of sodium, iodine, sulphur, phosphate of lime (?), silica, alumina, and magnesia.

When sponge has been cut into pieces, beaten in order to free it from little stones and shells, and burnt in a closed iron vessel, till it is black and friable, it is then called *burnt sponge* (*spongia usta*). As the virtues of this greatly depend on the proportion of iodine contained in the sponge, much of which is volatilised by the high temperature required in calcination, it has been proposed only to expose it to such a heat as will thoroughly dry, colour it brown, and render it friable, when it may be powdered, and preserved in well-closed bottles. For use it is generally formed into an electuary or into lozenges. A test of its goodness consists in heating it in a glass flask with sulphuric acid, and if copious violet-coloured fumes be evolved, this proves that it contains much iodine. Burnt sponge has been almost completely superseded in the treatment of bronchocele and scrofula by iodine and its preparations; but as it obviously consists of a natural combination of many of the principles which have been deemed useful in scrofula, it ought not to be hastily discarded. It is with great propriety retained in the Dublin Pharmacopœia.

SPONTANEOUS COMBUSTION. [COMBUSTION.]

SPORADIC (the Greek word *σποραδικός*, with the termination dropped) is a term applied to any disease which, being usually epidemic or contagious, occurs at any time in a few persons, without spreading extensively through a district. For example, in the year 1841 several cases of *sporadic* cholera occurred; that is, several persons, at different times and in different parts of the country, were affected with a disease in no respect different from the cholera which raged as an epidemic in 1832; but it did not spread beyond them by contagion, nor did it attack a number sufficient to give it the character of an epidemic. The circumstances on which the occasional occurrence of diseases that are usually epidemic, in a sporadic form, depend, are altogether unknown.

SPOUT, WATER. [WATER SPOUT.]

SPRAIN, or STRAIN, is an injury of muscular or tendinous tissues, resulting from their being forcibly stretched beyond their natural length. Its ordinary consequence is, after the first pain is gone by, to produce some degree of swelling, and a considerable dull aching pain of the injured part, which is greatly increased by any movement of it. These signs are due to an inflammation of the sprained tissues, which partakes of the slowness and obstinacy that characterise all the diseases of the tendons and ligaments, and which, if not early and duly attended to, frequently terminates in thickening, rigidity, and even more serious disorganisation of them and the adjacent parts.

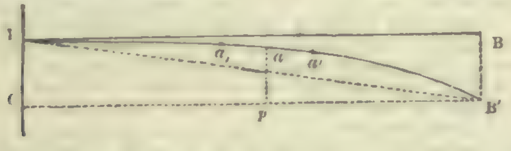
The treatment to be adopted for sprains is the immediate application of leeches, in number proportionate to the severity of the injury and the importance of the part. They should be repeated till the pain and swelling are distinctly decreased: the part should be kept perfectly at rest and cool, and the patient's general health should be kept or made good. When the pain has nearly ceased, and there remains little more than stiffness of the injured part, stimulating liniments (the common soap liniment, or a mixture of hartshorn and oil, for example) may be used.

SPRING. [SEASONS, CHANGE OF.]

SPRING, in Mechanics, is an elastic plate or rod, which is employed as a moving-power, or a regulator of the motions of wheel-work; also to ascertain the weights of bodies, or to diminish the effects of concussion.

The elder Bernoulli was the first whose attention was directed to the curvature assumed by elastic bodies, and he succeeded in resolving the problem in the case of a rectilinear plate being fixed at one end and bent by a weight applied at the other: it being assumed as a principle that, at any point in an elastic body, the force by which the body when bent by any power endeavours to recover its previous position is proportional to the angle of contact at that point; that is, to the angle which a tangent to the curve surface of the body makes, at the point, with that surface.

In order to give some idea of the manner in which the effects of elasticity are to be determined mathematically, let A B be a thin elastic plate immovably fixed at A, and bent into the form A B′ by a power P applied at B, and let $a_, a$, $a a'$ be two consecutive elementary portions of the bent plate: let also E represent the unknown force of elasticity acting perpendicularly to $a a'$ by which that element tends to recover the direction $a_, a$, from which it has been made to deviate by the power at B; and for simplicity let it be supposed that this power acts in the direction B′ C parallel to A B. Let fall $a p$ perpendicularly on B′ C; also represent B′p by x and $a p$ by y. Then, by mechanics $P.y$ expresses the momentum of the power at B′ to bend the plate at a, and in the case of equilibrium we have $P.y = E$. But E varies with the angle of contact, or the angle between the element $a a'$ and $a_, a$ produced, and that angle in any part of A B′ varies inversely with the radius of curvature at that part; therefore let r be the known radius of curvature at a point where the force of elasticity is given, and let this force be represented by e: also let R be the radius of curvature at a point, as a, where the force is represented by E. Then $\frac{1}{r} : e :: \frac{1}{R} : E$, or $\frac{er}{R} = E$, and putting E′ for er, we have $P.y = \frac{E'}{R}$. Substituting in place of R the differential expression for the radius of curvature, the elastic force might be obtained by the processes of integration. The integral, however, can only be obtained approximately.



If the elastic plate were in a vertical position with its lower end A resting on an immovable object, and a weight P, applied at the upper extremity B′, were to act in a direction towards A, the equations of the curve, approximately determined, are (the deflection being small)

$$y = \Delta \sin x \left(\frac{P}{E'}\right)^{\frac{1}{2}}, \text{ and } L = \left(1 + \frac{P.\Delta^2}{4E'}\right)h,$$

where x is any abscissa from B′ on the line B′A, y is the corresponding ordinate, Δ is the greatest deflection, or the ordinate at the middle point in B′A, h = B′A, and L is the length of the curve line AaB′: also the greatest weight which the plate or spring will bear without bending when pressed in that direction is expressed by $\frac{E'\pi^2}{L^2}$. ($\pi = 3{\cdot}1416$).

If P exceed by a small quantity the value of $m^2 \frac{E'\pi^2}{L^2}$, where m is any whole number whatever, the spring will make several bends crossing the straight line A B′ in $m - 1$ points between the two extremities.

When the elastic plate, in a horizontal position, is fixed at one end, as A, and the weight P, applied at the extremity B′, acts always vertically, the equation becomes (the deflection being small)

$$y = \frac{1}{E'}\left(\frac{1}{6}Px^3 + Cx\right)$$

where C is the tangent of the angle of contact at B′. If, on account of the smallness of this angle, C be neglected, it will follow, when x is made equal to B′C, that the whole deflection A C or B B′ will vary nearly with the weight P, and with the cube of the length of the spring.

The use of a spring as a moving-power may be best exemplified in its application to watch-work. The main-spring of a watch is a thin and narrow plate of well-tempered steel, which is coiled in a spiral form: one of its extremities is attached to a pivot or axle, and the other to the interior circumference of the cylindrical box in which it is contained. In being wound, the spring closes round the axle, and afterwards, in the effort by its elasticity to recover its former position, it turns the cylinder in a contrary direction: thus the chain which is attached to the exterior circumference of the cylinder and to the fusee causes the latter to revolve.

A slender and highly elastic spring of a like form is employed to produce a vibratory motion in the *balance* ring of a watch: one extremity of the spring is attached to the axle of the balance, and the other to some part of its circumference. If a movement of small extent about the axle be given in one direction to the balance, the spring will be compressed near the axle, and, in the effort to recover its previous state, the balance-ring will be moved round in a contrary direction; but the force of elasticity carries any point in the ring beyond the place which it occupies when the ring is in a state of rest; and when that force is destroyed by the compression again produced in the spring, near the axle, the balance is made to return in the direction in which it was first moved. Thus an alternate motion in the balance-ring is continued; the time of the vibrations, and consequently the velocities with which the wheels revolve, depending upon the force of elasticity in the spring. The elastic power of the spring varies with the tension, and is directly proportional to the angle through which the spring is wound about the axle; and thus the vibrations of a spring, like those of a pendulum in a cycloidal arc, are isochronous. [ELASTICITY.] The length of the spring and the diameter of the balance are increased by heat and diminished by cold; consequently, without some compensating power, the times of vibration will vary according to the changes of temperature.

When a carriage moving along a level road passes suddenly over an obstacle, so that a point in the circumference of the wheel is in contact with the obstacle, the centre of the wheel describes a circular arc about the point of contact as a centre; and then, if the carriage is perfectly rigid, a portion of its velocity will be lost. In order to maintain that velocity, an additional force of draught would be necessary; and an expression for this additional force is investigated in Whewell's 'Mechanics' (art. 261, and the following). Part of this additional force is employed in counteracting the motion of ascent, and the remainder, which is generally much the greater quantity, in diminishing the effect of the sudden change which takes place in the direction of the motion of the carriage. This latter part may be in a considerable degree removed by the use of springs; for then, on the wheel meeting the obstacle, the suspended body of the carriage bending the springs by its weight, the centre of gravity of that body is made to describe a curve line, to which its previous rectilinear direction is a tangent; and thus the jerks which arise from movements in directions making finite angles with one another are avoided.

The force of draught required in addition to that which is due to friction, when a stiff carriage passes over a roughly paved road, varies as the square of the velocity and the height of the stones directly, and as the radius of the wheel inversely.

SPRING-BALANCE. [BALANCE; DYNAMICS; WEIGHING-MACHINES.]

SPRING CARRIAGE. The progress of a wheel-carriage, even upon the best of roads, is impeded by the wheels coming in contact with, and being compelled to rise over, undulations of surface which check their rolling motion. In many old rough pavements, owing to the openness of the joints, and the wear of the stones, the road consists of a series of blunt ridges, in passing over which the motion of the wheel can be no other than a succession of jolts. The surface of a well-made road of broken stone, when in perfect order, presents few important asperities; but when metal or broken stone has been recently laid on, it is exceedingly rough. If a rigid carriage be drawn over any of these surfaces, the irregularities which affect the path of the wheels will be communicated through them to the body, to which they will impart a jolting or vibratory motion. In a four-wheeled carriage the movement of the body will be influenced by the discordant motions of the fore and hind wheels; and it will be continually liable, owing to the imperfections of the road, to have the whole of its weight thrown upon three wheels, whereby the framework will be exposed to injurious strains. To enable it to sustain such strains, the framework must be made very strong and heavy; and the destructive and painful effect of increasing the velocity of inelastic carriages would alone have been sufficient to limit the speed of vehicles.

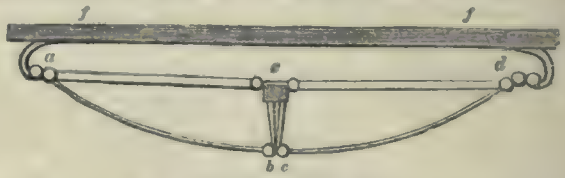
One of the simplest means of alleviating concussion is that often adopted in light carts, of suspending the seat from the sides of the body by leather straps. Next to this is the use of straps to suspend the body itself, an expedient which seems to have been occasionally resorted to from an early period. With very few exceptions, it appears that slung or suspended carriages were not used until the 17th century. In the early carriages of this kind the straps were usually attached to a framework of wood at each end of the vehicle, rising to a considerable height above the axles. The antique four-wheeled carriages of Europe used for state purposes are mostly constructed on this plan; and their great weight and slow movement prevent any violent concussion. A serious disadvantage of this construction is the great length of carriage that it renders necessary, and the cumbrous character of the wooden framework which supports the braces. The carriage must also be heavily loaded, in order to make the motion tolerably comfortable, especially when the straps are suspended from points not much higher than the bottom of the body. To remedy the defects of the primitive slung carriage, it was desirable to render the pillars from which the straps were suspended somewhat elastic. This could not be readily effected with wood, because the pillars were necessarily short, and therefore stiff. Hence arose the use of elastic steel supports, which have gradually assumed the form now well known as C-springs.

Straight springs of steel probably owe their origin to the straight wooden springs occasionally used in light vehicles in this and other countries. Used either singly or in combination, they afford sufficient elasticity for many purposes, without raising the body to an inconvenient degree, or interfering with its form; since they may be placed entirely beneath it, and require but little room for their play. *Elliptical* springs have, in some degree, the same advantages; but they require rather more depth than straight springs.

Carriage-springs are usually formed of several thin plates of steel, of various lengths, so laid and fastened together that the spring shall be thick in the centre, or at the end by which it is fixed, and thin, or consisting of only a single plate, at the end or ends where the greatest play is required. The steel used is of coarse quality, and has little carbon in its composition. It is fashioned by rolling-machinery to the transverse dimensions required, which vary from one inch and a half to three inches in width, by one-eighth of an inch to half an inch in thickness. The plate forming the back of the spring is usually thicker than the rest, on account of its being the longest, and having its ends formed into bolt-eyes, to receive the bolts by which the body is connected with it. With this exception, it is not usual to make any difference in thickness in the several plates of a spring, notwithstanding their different lengths. After the plates have been wrought into the form required, they are hardened by heating in a hollow fire, and then plunging into water. They are subsequently tempered by drawing them again through the fire, until they become so hot that a stick rubbed over the surface will be kindled to a blaze. Any accidental warping acquired in these processes is removed by hammering, the plates being slightly warm during the operation, to avoid the risk of breakage. They are then finished by filing all the parts that will be exposed to view when the spring is complete; and are finally put together and secured by a square hoop of iron, which is shrunk on hot, and by a rivet passing through the hoop and through all the plates.

Coach-makers apply distinct names to a great many varieties of springs; but those which are most generally used may be briefly enumerated. The straight spring, if single, is the *single-elbow spring*. The *double-elbow spring* is a straight spring, acting on both sides of the fixed point. It is a kind of spring very extensively used in stage-coaches, omnibuses, and light two-wheeled vehicles. *Elliptic springs* are used single in some carriages, between the axle and the framework; the spring resting on the axle, and being connected with the carriage by means of a curved bar of iron, called a *dumb-iron*, placed over it like another spring. The spring is then called an *under-spring*. Elliptic springs are often used in pairs, under the name of *nut-cracker springs*, the two springs being hinged together at each end, so as to form a long pointed ellipsis. In this way elliptical springs are much used in such four-wheeled carriages as have no perches. *C-springs* consist of two-thirds of a circle, lengthened out into a tangent; the tangent being laid horizontally, and bolted down to the framework of the carriage. When these springs are used, the body is not, as in most other cases, connected immediately with the springs, but is suspended by leather straps, which pass round the back of the springs, and are fastened to the framework near to their base. *Telegraph-springs* are combinations of straight springs in sets of four. Two are placed longitudinally, resting either immediately upon the axles, or upon the lower framework of the carriage; and two others, placed transversely, are suspended from their ends by shackles. The body is supported upon the centres of these transverse springs. *Tilbury-springs* are another combination of straight springs. Two single-elbow springs are attached to the hinder part of the body, and suspended by leather braces from a transverse spring elevated on an iron standard at the back of the framework. The front of the body is suspended from the shafts by two single-elbow springs with short leather braces; and sometimes a pair of double-elbow springs are interposed between the shafts and the axle. *Dennet-springs* are a combination of three straight springs, two of them placed across the axle, and attached at their fore ends to the shafts or the framing of the body, and the third placed transversely, suspended by shackles from their hinder extremities, and fastened to the body at its centre. The bodies of private cabriolets are usually hung upon *C-springs*, with small curved springs in front, and double-elbow springs frequently added between the shafts and the axle. The combination of springs used in under-spring carriages is the most effective which has yet been discovered for producing the minimum of concussion or motion to the passengers. The body of such a vehicle is suspended by braces from C-springs; and the framework of the carriage to which the C-springs are fastened, is supported upon under-springs, which intercept concussion from the unevenness of the road.

Of these various springs, none but the C-springs with leather braces allow universal motion to any important extent. In some carriages loops of leather or caoutchouc have been used, instead of iron shackles, for connecting straight springs, by which means the motion is rendered pleasanter, and the rattling noise of the shackles is avoided. Another defect of ordinary springs is their want of adjustibility to the weight they have to carry. They must, of course, be made strong enough to sustain the maximum weight they are intended to bear; but, by being so, they become too stiff to play easily under a light load. To meet the deficiencies of the springs in common use, Mr. Bridges Adams contrived one on the principle of the bow, which will yield in any direction, and may be made capable of adjustment, by means of screws, to a light or heavy load. This spring consists of a single plate of well-tempered steel, forced into a curved form by the tension of a chord of prepared hempen rope, or of a riband of iron or steel, and to which the axle is attached. There are two bow-springs, *a b* and *c d*, connected with each other and with the same axle. These are jointed together at *b c*, and attached to the body, of which the lower framing is shown at *f f*, by movable joints at *a* and *d*, which allow the springs to lengthen and shorten in playing. The chord of each bow is in two parts of unequal length, each of which is connected at one end with the bow, and at the other with the axle at *e*; so that the chord of the bow, *a b*, takes the direction *a e b*, and that of the bow, *c d*, the direction *c e d*. Among the advantages claimed for them are their lightness and extreme elasticity, arising from the superior quality of the steel, and the absence of the friction which attends the action of the common laminated springs.



All the springs that have been alluded to in this article are *bearing-springs*, for supporting the weight of the body of the carriage, and of the load which it conveys. In ordinary carriages no other springs are used; but in those employed upon railways, springs are also used to impart elasticity in the direction of the line of draught, so as to render the starting and stopping of the carriages gradual and easy.

SPRINGS. Rain and snow fall in quantities so unequal in different districts, and on soils which exercise upon them such various influences, that the phenomena of springs, which are primarily dependent on the penetration to some depth in the earth of water which was absorbed at the surface, are extremely complicated and curious. It is very interesting to geologists to classify and determine the causes of these phenomena, and very important in agriculture and the arts to acquire a power of directing the water currents in and below the soil and strata. The art of draining consists essentially in giving to the diffused and injurious springiness of particular soils and situations a concentrated, perhaps beneficial, current; while artesian wells relieve the hydrostatic pressure prevalent at great depths, and yield copious streams in dry lands and deserts.

As a general rule, springs are permanent in proportion to the depth to which the water which supplies them has descended from the surface; they are perennial and almost invariably constant in temperature and volume, whether hot or cold, copious or full, in situations where, from the arrangement of the mineral masses of the globe, deep subterranean channels exist for the reception of rain, and particular impediments direct and contract the passages of reflux to the surface. Such cases are common in stratified countries where jointed limestones or sandstones receive water at elevated points on the surface, and conduct it downwards below strata of clay, which are only pervious at a few points, and there permit natural discharges at lower levels than the recipient surfaces. Frequently these argillaceous strata are so nearly impervious, that artificial perforations relieve the pressure of the subterranean columns of water better than the few natural points of efflux, and thus pits and levels excavated for mines may drain springs at some distance.

On the contrary, in a country which contains narrow and frequently mixed masses of clay and gravel, or clay and sand, which cover the solid rocks, concentrated springs are almost absent, but there is a prevalent humidity and diffused springiness along the limit of the gravelly or sandy tracts. After a continuance of dry weather such springs and wetness disappear, to be renewed after the next fall of rain.

The particular points at the surface where springs, or "wells," as they are often called in the districts where somewhat of the Saxon elements of our language remains (*quelle*, in German, signifying not what is commonly understood by the English word "well," and the

French "puit," but a spring), are determined in general by one of three things :—

1. They occur at the point of lowest level, on the edge of the impervious clay which dams up the water. This happens in the cretaceous and oolitic districts of England.

2. They are often dependent on the lines of great joints, or fissures of the rocks, produced in the course of the consolidation and shrinking of the mineral masses. Large springs are thus poured out of the mountain-limestone of England.

3. The waters are directed to the surface by lines of fault, which are often quite impervious to water, and traverse the rocks in vertical or inclined planes. The hot springs of England and Wales are mostly thus circumstanced.

In general, then, the water which issues from the earth in one copious spring has been received by minute absorption on a large surface: as the living tissue of a sponge receives water by absorption through the numerous pores, collects it internally in a few channels, and rejects it by a very limited number of orifices, or as the capillaries collect blood for the veins, and these supply the heart, so the porous texture and channelled structures of rocks permit that continual circulation of water below the earth's surface, on which, in a great degree, its habitable character depends.
